denaturation is a central harmful factor for the cell during stress. Thus, the mechanisms for preventing protein denaturation, and for reversing it when it is still reversible, are major survival tools for the cell. Among these tools, the stress proteins, including the

molecular chaperones, are prominent. Therefore, it is not surprising that the levels of these proteins are maintained or augmented in response to stress, whereas many other proteins decrease or become undetectable.

There are several ways for the cell to readjust the concentration of stress proteins when it has been affected by a stressor. One way is to upregulate the genes that produce the useful proteins, and another is to diminish the degradation of the latter. All cellular proteins undergo a cycle of birth, maturation, function, and degradation (equivalent to death). By postponing the degradation of stress proteins, the cell enhances the chances of its survival in the face of stress.

Another mechanism for increasing the levels of useful proteins during stress is to facilitate their synthesis from their mRNAs. This may be achieved in various ways. One way is to increase the life span of the mRNAs that encode stress proteins (mRNAs are usually short-lived). If the stability of the mRNA increases, the same mRNA molecules can reach the ribosome and be translated more than just once, avoiding delays due to the unavailability of newly synthesized mRNA molecules. Furthermore, translation itself may be enhanced, so mRNA is decoded more rapidly and more mRNA molecules are translated per ribosome.

In summary, gene activation, involving both an initiation of the transcription of genes inactive in the absence of stress and an increase in the rate of transcription of genes already active before stress, is not the only mechanism that brings about the increase of heat shock proteins. Prolongation of the life span of mRNAs and of the stress proteins themselves also plays a role in building up the cellular defenses against the ravages of stress.

Clearing the Rubble

The rescue of proteins partially damaged by stress is a key mechanism for cell survival, as explained earlier. However, many molecules may be damaged irreversibly and cannot be rescued. These denatured proteins tend to aggregate and to form relatively large precipitates. These may be toxic, and they may also obstruct other cellular components. This is the reason why the cell has a battery of enzymes that digest seriously damaged, useless proteins. These enzymes are called proteases, and some of them are considered stress proteins because they handle the key task of removing stress-damaged proteins to clear the way for the trafficking and functioning of other, viable molecules essential for survival. Furthermore, the degradation products generated by the action of proteases on their substrates serve as building materials

for the synthesis of other molecules necessary for mounting a stress response.

In summary, a series of mechanisms are set in motion by stress. The main objective of the cell is to maintain a range of functionally competent proteins at the concentrations required for survival. The production of nonessential proteins is stopped, the synthesis of required proteins is started or increased, and damaged or useless molecules are eliminated.

Milestones

The heat shock response has been the focus of research efforts for at least 4 decades. If we bear in mind the current division of living organisms into three major lines of descent or phylogenetic domains – Eucarya (eukaryotes), Bacteria (eubacteria), and Archaea – it is possible to see that the chronology of specific contributions proceeded from the Eucarya to Bacteria, and only considerably later reached the Archaea. Currently, organisms from the three domains are used as experimental models, but those from the Archaea are still in the minority.

In 1962 it was reported that a temperature elevation induced distinct puffing patterns in the chromosomes of the salivary gland of the fly *Drosophila buschii*. These puffs were transient but reproducible, and they always affected the same chromosomal regions (bands). Puffing occurred when the fly larvae were moved out of their optimal temperature for growth (i.e., 25°C) and into a temperature of 30°C and kept there for 30 min. The same results were obtained with another fly species, *D. melanogaster*, which is much used for research.

At the time, these results were interpreted to represent gene activation induced by a change in the environmental temperature, which as we know now is what constitutes a heat shock response. Similar effects were obtained with 2–4 dinitrophenol and salicylate, two compounds that today we would call chemical cell stressors (see [Table 1](#)). These observations established that heat shock activates some genes, always the same ones in a defined location in the chromosome, and that similar gene activation can be induced by agents other than heat. The conclusion was that heat shock and other stressors induce gene transcription with production of new mRNAs.

That these mRNAs were actually the precursors of new proteins, whose synthesis was set in motion by heat shock, was demonstrated in 1974, once again in the salivary glands of *D. melanogaster* and also in other tissues. The results showed a correlation between the typical heat shock-induced puffing patterns, mRNA synthesis, and the appearance of several new proteins in the tissues of the fly.

The new proteins were visualized by one-dimensional gel electrophoresis. At this time, it became clear that heat shock induces the synthesis of proteins that are not present at detectable levels under normal physiological conditions. It also became clear that gene activation and protein synthesis are not restricted to a single tissue or organ (e.g., the salivary glands) but are more generalized.

The main characteristics of the heat shock response were in fact defined by these early studies with the fruit fly. These characteristics are the transient activation of a restricted, defined group of genes by an abrupt temperature upshift with the synthesis of a set of mRNAs and proteins, occurring in all types of tissues and cells. Similar effects can be produced by other agents or stressors.

Thus, the field of heat shock or stress response was opened for further investigations at the biochemical, molecular, and genetic levels by these pioneering studies on a eukaryotic organism, an insect. Several years passed before knowledge of the stress response of prokaryotes began to emerge. The prokaryotic organism most used for research in the field has been the bacterium *Escherichia coli*. Investigations with this model system were reported from the beginning of the 1980s. A number of stress genes and proteins were identified, and many of them have been characterized thoroughly, including detailed structure–function determinations by very sophisticated techniques such as crystallography, electron microscopy, and computer-assisted imaging analysis. Also, considerable progress has been made toward the elucidation of the mechanisms that regulate stress genes, addressing the following questions. How are these genes instructed to start transcription, and to stop it, according to the cell's needs? How does the cell sense the temperature or other environmental changes (stressors) around it and transmit from its surface the orders for activity or inactivity to the genes?

Over the years, since the time of the initial studies with *E. coli*, other bacterial species have been added to the list of model systems used for studying the stress response. These species include representatives from many of the known bacterial groups, such as gram positives and gram negatives; mesophiles, thermophiles, and hyperthermophiles; and pathogens and nonpathogens (see Table 2). In parallel, eukaryotes other than *Drosophila* have also been used to study the stress response and the stress genes and proteins. Examples are the single-celled fungus *Saccharomyces cerevisiae*, known also as baker's yeast, and several other organisms representing the major groups of eukaryotes (see Table 2).

These studies with members of the domains Bacteria and Eucarya proliferated in the 1980s and 1990s,

not only because they helped to advance our understanding of important cellular functions and mechanisms under physiological conditions and during and after stress (see Table 3) but also because some of the organisms are pathogens for humans and for animals valued by humans. Hence, it was pertinent to examine the role of the stress response in health and disease. In addition, other model organisms have existing or potential industrial applications and are, therefore, of commercial interest.

While the research activities mentioned so far were ongoing, the identification and characterization of the third evolutionary domain, the Archaea, proceeded steadily since the late 1970s. However, it was only in 1991 that a heat shock gene, *hsp70(dnaK)*, was first identified by cloning and sequencing in an organism of the domain Archaea, the mesophilic methanogen *Methanosarcina mazei*. In the same year, the chaperonin complex called the thermosome was visualized in another member of the Archaea, a hyperthermophile. Both findings opened the doors to exciting new territories for exploration. Research with archaeal organisms has progressed, driven by the same motivations that propelled research on organisms of the other two domains. Archaeal species are attractive to the scientist because they possess a series of characteristics that are unique to them and that were unknown before these organisms were discovered. Some of these characteristics are extreme compared with what is known for the more familiar, and better studied, eukaryotes and bacteria. In addition, there are archaeal species and molecules from Archaea that have potential in the biotechnology industry, including the development of clean and efficient means for waste treatment with the generation of useful or harmless by-products. In a variety of these applications, the stress response and the stress genes and proteins play a key role. Consequently, their manipulation is a promising way to improve extant technology and develop better alternatives than those currently available.

Currently, research continues on organisms of the three domains. The goals are to discover other stress genes, to characterize more thoroughly the mechanisms that bring about the stress response and the mechanisms involved in the regulation of the stress genes, and to design strategies and procedures to manipulate these genes and their protein products to prevent or cure lesions caused by stressors in plants and animals (see Table 4).

New Developments to 2005

Recent developments pertain to (1) stress genes in the Archaea; (2) chaperones and disease; (3) genomics

and automated methods by which sequenced genomes can be studied and by which large amounts of information about expressed genes (including stress genes), their regulatory networks, and the interactions of their protein products in the cell can be obtained and analyzed; (4) high-throughput technology to measure gene transcription at the level of the entire genome and to determine the full range of proteins present in a cell or tissue at any given time; and (5) techniques to measure the presence of stressors in environmental samples such as wastewaters, soil, food, paints, and construction materials.

Stress genes in Archaea proved to have a distribution unexpected from what was known from bacteria and eukaryotes. For example, the molecular chaperone machine Hsp70(DnaK)-Hsp40(DnaJ)-nucleotide exchange factor, which is present in all bacteria and eukaryotes tested, was not found in several archaeal species. Furthermore, the chaperonin system group I, which had been considered to be exclusive to bacteria and bacterial-related eukaryotic organelles, was discovered in some species of Archaea. Two new chaperonin group II subunits were discovered in an archaeal species. This finding elevated the total number of subunits in the Archaea to five (the maximum known before was three), approaching a total number of eight, which is characteristic of eukaryotes.

The concept that defective molecular chaperones can contribute to pathogenesis not only as auxiliary factors but also as primary etiological agents was developed, and a number of diseases were identified as examples of this newly recognized pathological entity, chaperonopathy. The negative impact of chaperonopathies on stress responses, on survival in the face of protracted stress, and on recovery after stress remains to be evaluated. This will most likely be an area of intensive research in the first decades of the twenty-first century.

High-throughput automatic technologies with relatively low turnaround times were developed for sequencing genomes, which increased considerably the information available in databases. In parallel, similar, automated methods were standardized for mining genome sequences for stress genes and their regulatory genes and DNA elements, and to obtain clues on the multiple interactions of stress proteins and molecular chaperones with other proteins and cell components (systems biology and cellular neural networks) and with foreign compounds. The results of these genomic, computer-assisted searches will be instrumental in guiding laboratory experiments, focusing on a few selected genes and proteins for elucidating their functions, regulation, and interaction *in vitro* and *in vivo*.

Also, microarray technology has radically changed the analysis of gene expression profiles at the whole genome level. Microarray analysis provides enormous quantities of data for the comparison of different tissues from healthy and sick organisms or of cells under basal conditions (constitutive gene expression) and cells affected by stressors (stress-induced gene expression). This approach has shown that the number of genes induced by stressors is relatively large considering the total number of genes in any given genome, encompassing not only the genes that encode the classic Hsps and chaperones but also many others whose products have a variety of other roles. Thus, it has become clear beyond doubt that there are many stress genes and proteins but that only a fraction of them belong to the Hsp and chaperone families. Likewise, it is clear that not all molecular-chaperone genes are induced by stressors and, therefore, not all chaperones can be classified as Hsps.

The increasing concerns about the contamination of the environment and food with toxic compounds (i.e., cell stressors) have given impetus to the development of novel assays for measuring the potency of these compounds for causing cell stress.

Perspectives

In addition to the stressors discussed in the preceding sections, psychological stress due to professional, financial, social, and family pressures and obligations also cause cell stress via the hormonal and biochemical imbalances inherent in this unpleasant condition. The list of stressors becomes longer and longer as new compounds are isolated from natural sources or are synthesized in the laboratory and released into the environment (added to water, foods, fuels, paints, building materials, clothing, etc.). The hole in the ozone layer of the atmosphere and the greenhouse effect add another dose of stressors (radiation and overheating) on top of all the others already alluded to. No doubt plants and animals – including humans – will have to face stress as the scourge of our time. The more that is known about the heat shock (stress) response, the easier it will be to find ways to counteract the effects of stressors. Research in this field promises to be vigorous in the near future and will most likely attract many scientists. The topic should also be of interest to virtually everybody, regardless of educational level or profession. The public at large ought to know, at least in a general way, what can cause cell stress and how to avoid stressors and abate their deleterious effects. For these purposes, the usual means of using good hygiene and common sense should be helpful, along with efforts to promote legislation aimed at reducing the number and quantities of stressors.

The malfunctioning of antistress mechanisms has recently come into prominence as a new field of medicine. For example, abnormalities in chaperone molecules have an impact on the chaperoning systems throughout the organism and have been implicated in various genetic and acquired pathological disorders. This new medical field will no doubt attract the attention of more and more scientists and practitioners to improve diagnostics, therapeutics, and prevention.

Hemostasis Factors and Cardiovascular Disease

Acute Stress

Chronic Stress

Conclusions and Future Directions

Glossary

<i>Blood coagulation</i>	Physiological process as part of hemostasis in which liquid blood is changed into a blood clot of platelet aggregates and fibrin.
<i>Endogenous anticoagulants</i>	Proteins produced by the body to regulate thrombin activity during blood coagulation.
<i>Fibrinolysis</i>	Physiological process of hemostasis in which the fibrin clot is broken down.
<i>Hemostasis</i>	Physiological process in which bleeding is halted in a damaged blood vessel requiring the combined regulated activity of vascular, platelet, and plasma factors.
<i>Hypercoagulability Platelets</i>	A shift in the hemostatic balance favoring formation and maintenance of a clot. Small anuclear blood cells that adhere to sites of blood vessel injury, where they become activated and aggregate with each other.
<i>Thrombosis</i>	Pathological process in which a blood clot forms in the lumen of a blood vessel.

Historical Perspective

The possible influence of stress and stress hormones on blood coagulation and fibrinolysis has attracted researchers for more than a century. As early as 1903, Vosburgh and Richards observed that epinephrine added to the surface of the pancreas and injected into the abdominal cavity of dogs hastened the coagulation time of whole blood, in some cases to as much as four-fifths the coagulation time of control animals. In 1911, von den Velden reported a similar decrease in coagulation time in humans after subcutaneous injection of epinephrine. Only a few years later, Walter Cannon and his co-workers demonstrated in a series

of carefully conducted experiments that stimulation of the splanchnic nerve, pain, fear, and enrage ment all shortened blood clotting in the cat. They noted that rapid coagulation did not occur if adrenals had been removed or were exhausted because of previous excitement, when cats had been caged near dogs. These observations prompted Cannon to state that “rapid coagulation may reasonably be considered as an instance of adaptive reaction serviceable to the organism in the injury which may follow the struggle that fear or rage may occasion.”

Patients with hemophilia A lack substantial activity of clotting factor VIII (FVIII:C) such that severe bleeding occurs with minor traumas or even spontaneously. In search of treatment options for this bleeding disorder, systematic investigations in the 1960s and 1970s found that parenteral administration of epinephrine evoked a dose-dependent increase in plasma levels of antihemophilic FVIII:C with concomitant shortening of the clotting time of whole blood. Electric brain stimulation evoked an increase in plasma FVIII:C and a corresponding decrease in the clotting time in dogs. Plasma FVIII:C also rose after air inflation in the skull during a diagnostic procedure in humans. In terms of fibrinolysis, anecdotal reports from the 1940s observed fibrinolytic activation by epinephrine and by a variety of acute naturalistic stressors eliciting a fear response, e.g., planned surgery, air raid warning, and exams.

These earlier studies suggested what has become consensus today, namely, that in a healthy organism, acute stress concomitantly activates the coagulation and fibrinolysis part of hemostasis to result in net hypercoagulability. Clearly, this supports Cannon, who argued that thickening of blood in response to an acute and potentially life-threatening stressor is actually physiological and provided our ancestors with an evolutionary benefit. Indeed, we can readily imagine that hunters who were injured and women who gave birth increased their odds of surviving if hypercoagulability constrained excessive bleeding. Equally exciting, some of this early research can be viewed as first evidence for a regulatory mechanism of hemostasis by the brain involving the sympathomedullary axis and catecholamines.

Hemostasis Pathways

The scheme in [Figure 1](#) simplifies complex and closely intertwined hemostasis pathways. Activation of hemostasis results in a sequential interaction between

Figure 1 Hemostasis pathways. The figure shows coagulation steps in solid lines and fibrinolysis steps in dashed lines with the symbol $\rightarrow$ meaning activation of a step and the symbol $\mid$ meaning inhibition of a step. Hypercoagulability markers thrombin-antithrombin (AT) III complex (TAT) and clotting factor V (FV) and X (FX) are involved in both coagulation pathways. FXII, FXI, FIX, and FVIII are components of the intrinsic pathway, and tissue factor (TF) and FVII belong to the extrinsic pathway of blood coagulation. PAI-1, plasminogen activator inhibitor-1; t-PA, tissue-type plasminogen activator. Cf. text for details of activation steps.

enzymes and inhibitors of the coagulation and fibrinolysis cascades, of platelets, and of the von Willebrand factor (VWF). Two pathways of blood coagulation are commonly distinguished. Whereas the intrinsic pathway is initiated by FXII, the extrinsic pathway is triggered when tissue factor becomes exposed to the bloodstream at sites of tissue damage, e.g., on material of a ruptured atherosclerotic plaque. Tissue factor instantly binds to circulating FVII. Both pathways result in activation of several clotting factors in a sort of cascade, and eventually converge in a common activator complex. This complex converts prothrombin to thrombin, which, in turn, converts fibrinogen to fibrin. Together with platelet aggregates, fibrin forms a blood clot that, e.g., may critically occlude a coronary artery to result in myocardial infarction. Circulating VWF mediates adherence of platelets to sites of blood vessel injury where platelets are activated and aggregate with each other through fibrinogen bridges. Negatively charged phospholipids on activated platelets catalyze activation of circulating clotting factors.

Termination of clot formation involves several anticoagulant steps, e.g., binding of antithrombin III to thrombin. This step neutralizes thrombin, a potent activator of several clotting factors and platelets, in a thrombin/antithrombin III (TAT) complex. Fibrinolysis is initiated by tissue-type plasminogen activator (t-PA) converting plasminogen into fibrin-cleaving plasmin. The breakdown of cross-linked fibrin chains yields soluble fibrin fragments such as D-dimer. The antifibrinolytic enzyme plasminogen activator

inhibitor-1 (PAI-1) is the main inhibitor of t-PA, neutralizing t-PA in a t-PA/PAI-1-complex.

TAT and D-dimer are viewed as coagulation activation markers because they combine several coagulation steps leading to thrombin and fibrin formation, respectively. In addition, TAT and D-dimer are hypercoagulability markers indicating exaggerated coagulation activity. It is important to note that, unlike individual clotting and fibrinolysis factors, D-dimer indicates activation of the entire hemostatic system, i.e., fibrin formation by the coagulation system and fibrin degradation by the fibrinolytic system.

Hemostasis Factors and Cardiovascular Disease

Since the mid-1980s, numerous large-scale and prospectively designed epidemiological studies have been published suggesting that numerous components of the hemostatic system may predict cardiovascular disease. Most of this research has investigated the predictive value of hemostasis factor for coronary artery disease (CAD) and acute myocardial infarction, while a minor proportion of previous work has addressed the role of hemostasis factors in cerebrovascular and peripheral arterial disease. Meta-analyses have shown CAD risk factor status for fibrinogen, D-dimer, and VWF, whereas FVII:C, FVIII:C, TAT, PAI-1, t-PA, and platelet activity were risk factors of CAD and myocardial infarction across a series of individual investigations.

Remarkably, hemostasis factors not only predicted recurrent cardiac events in patients with cardiovascular diseases but also prospectively predicted the cardiovascular disease risk in individuals who were in apparently good health at study entry. Moreover, many studies showed that the prospective relationship between hemostasis factors and coronary events was independent of sociodemographic factors, lifestyle factors, and the established cardiovascular risk factors of smoking, diabetes, hypertension, and obesity, all of which may affect hemostasis. Altogether, this abundant epidemiological research challenges the view of some researchers that hemostasis factors are mere risk markers of cardiovascular disease and do not actively contribute to atherosclerosis.

It is assumed that a procoagulant milieu, as reflected by increased activity of clotting factors, coagulation activation markers, platelets, and the VWF on the one hand and impaired fibrinolysis on the other, will gradually contribute to atherosclerosis progression over many decades by promoting fibrin deposits in the atherosclerotic vessel wall and inflammation. In addition, upon rupture of a vulnerable atherosclerotic plaque, a procoagulant milieu may accelerate

and enhance intravascular thrombus growth and critical occlusion of a coronary artery. Chronic low-grade systemic activation of coagulation processes with chronic stress and repetitive hypercoagulability in response to daily hassles, for example, thus provide one psychobiological pathway through which stress might accelerate atherosclerosis progression. Moreover, the stress procoagulant response is exaggerated in atherosclerotic vessels because the endothelium has become dysfunctional and partially deprived of its anticoagulant properties. Therefore, an exaggerated stress procoagulant response could enhance thrombus formation at times of plaque rupture triggered by acute stress-induced blood pressure peaks.

Acute Stress

Summary of Findings

Table 1 summarizes findings from well-conducted and standardized laboratory studies on acute stress effects on hemostasis factors in apparently healthy subjects reaching beyond individual findings. Different types of speech tasks, mental arithmetic, the mirror star tracing task, and the Stroop color-word conflict test were regularly applied as mental stressors in these studies. This research suggests that acute stress elicits a significant increase both in procoagulant factors (i.e., FXII:C, FVII:C, FVIII:C, fibrinogen, VWF, platelet activity) and in profibrinolytic t-PA. However, the finding of an increase in coagulation activation markers TAT and D-dimer suggests that the concomitant activation of virtually all hemostasis components with acute stress results in net hypercoagulability compatible with the evolution paradigm of Cannon. Unlike changes in blood pressure and cortisol, changes in the coagulation system do not adapt in response to the same stressor (i.e., combined speech task and mental arithmetic) applied three times on healthy subjects within an interval of

1 week. Apparently, evolution empowered humans to mount the same hypercoagulability any time we might potentially be injured independently of whether or not we perceive the situation as threatening.

Modulators of the Procoagulant Stress Response

Certain diseases, psychological states, and life circumstances have been shown to exaggerate the acute stress procoagulant response. In particular, it has been shown that D-dimer formation is increased and fibrinolytic activation is attenuated in acutely stressed patients with cardiovascular disease. Also, recovery of platelet activity after stress was delayed in patients with CAD as compared to those without. Anxiety, depression, and poor coping strategies (i.e., low problem solving and low personal mastery) have been shown to be associated with greater D-dimer formation and antifibrinolytic activity with acute stress in elderly subjects who were caregivers for a spouse with Alzheimer's disease. These caregivers also experienced greater acute procoagulability to stress when they experienced relatively more negative life events in the preceding month and if their spouse showed relatively more severe dementia. In accordance with the stress reactivity paradigm, these findings suggest that the stress procoagulant response, because of being hyperactive, might embed potential cardiovascular harm in certain individuals with certain diseases and at certain times of their life.

However, hemostatic effects of negative affect are not straightforward and may differ between elderly individuals, many of whom have cardiovascular disease, and healthy individuals. In the latter, an inverse relationship was found between levels of different domains of negative affect (e.g., anxiety and depression) and the magnitude of coagulation changes with acute stress. We may assume that endothelial dysfunction in the elderly might interact with negative affect to promote acute hypercoagulability. In contrast, greater hypercoagulability with less negative affect might still reflect normal physiology in healthy individuals preparing the organism for fight or flight.

Table 1 Changes in hemostasis factors with stress

Hemostasis factor	Acute stress	Chronic stress
FVII:C	↑	↑
FXII:C	↑	
FVIII:C	↑	
Fibrinogen	↑	↑
Thrombin/antithrombin III complex	↑	—
D-dimer	↑	↑
von Willebrand factor	↑	↑ / —
Platelet activity markers	↑	
Plasminogen activator inhibitor-1	—	
Tissue-type plasminogen activator activity	↑	↓

↑, increases with stress; ↓, decreases with stress; —, no response to stress.

Physiological Mechanisms

Molecular studies in *in vitro* and *in vivo* studies in animals and humans convincingly demonstrate that the sympathetic nervous system (SNS) regulates hemostatic activity. Much of this knowledge derives from human studies in which adrenergic compounds, particularly the stress hormones epinephrine and norepinephrine, had been infused together, with or without previous blockade of adrenergic receptors by various drugs. **Table 2** summarizes adrenergic receptors and mechanisms assumed to be involved

Table 2 Adrenergic receptors and hemostasis regulation

<i>Hemostasis factor</i>	<i>Adrenergic receptors (ARs)</i>	<i>Mechanisms</i>
FVIII	Endothelial β 2-AR	Release from endothelial cells and the liver
VWF	Endothelial β 2-AR	Release from endothelial cells
t-PA	Endothelial β 2-AR	Release from endothelial cells
	(β 1- and) β 2-adrenergic stimulation	Increases t-PA clearance
	α 1-adrenergic stimulation	Reduces t-PA clearance
Platelets	Platelet α 2-AR	Platelet activation
	Platelet β 2-AR	Inhibition of platelet activation
PAI-1	β 1- and/or β 2-adrenergic stimulation	PAI-1 mRNA expression

FVIII, clotting factor VIII, VWF, von Willebrand factor, t-PA, tissue-type plasminogen activator; PAI-1, plasminogen activator inhibitor-1.

in hemostasis regulation. Via stimulation of vascular endothelial β 2-adrenergic receptors, catecholamine surge releases preformed FVIII, VWF, and t-PA from endothelial storage pools into the circulation. This phenomenon takes place within minutes and shows dose dependency. Catecholamines also stimulate release of FVIII from the liver and affect hepatic clearance of t-PA. In addition, platelets are activated by stimulation of their α 2-adrenergic receptors, with platelet β 2-adrenergic receptors likely exerting an inhibitory effect on platelet activation by catecholamines. Greater sensitivity of the β 2-adrenergic receptor was associated with greater thrombin formation in response to acute stress.

Stress-induced hemoconcentration was not associated with acute stress-induced changes in coagulation factors and activities. This suggests that coagulation activation during stress is an active phenomenon and does not merely reflect a passive increase of factors due to stress-induced plasma volume contraction. To date, there is little evidence for a significant effect of the hypothalamic-pituitary adrenal (HPA) axis and cortisol activity on the acute stress procoagulant response. Conceivably, evolution wanted the blood to clot instantly after injury as mediated by the SNS. In contrast, the HPA axis peaks its activity only 15 to 30 min after stress and, therefore, is a system likely too slow to critically limit bleeding.

Chronic Stress

Summary of Findings

Table 1 shows that, as with acute stress, chronic stress leads to an increase in procoagulant factors, namely, FVII:C, fibrinogen, and D-dimer, while data for VWF are conflicting. Notably, effects of chronic stress on fibrinolytic activity are distinctly different from those observed with acute stress. Chronic stress impairs the fibrinolytic activity such that the balance between procoagulant factors and profibrinolytic factors is shifted toward hypercoagulability to an extent that

exceeds the physiological net hypercoagulable changes seen with acute stress in healthy individuals.

These findings derive from investigations on hemostasis factors in subjects with high job strain, with low socioeconomic status, and who are caregivers of a demented spouse. In these studies, job strain was mainly defined as a mismatch between job demands and decision latitude and an imbalance between effort spent and reward obtained, moderated by a personality trait of overcommitment to work. Although relationships between various job strain variables and elevated plasma levels of FVII:C, fibrinogen, and PAI-1 on the one hand and decreased t-PA activity on the other were independent, most of the association between low socioeconomic status and hypercoagulability became insignificant when statistics controlled for health habits.

The number of negative life events in the preceding month correlated positively with plasma D-dimer in Alzheimer caregivers. In another study, chronically stressed dementia caregivers had higher D-dimer levels than age- and gender-matched noncaregiving controls, even when controlling for cardiovascular diseases and risk factors, lifestyle, and medication. Increased D-dimer was also observed in elderly hypertensive subjects in the weeks after they had experienced catastrophic stress. A fairly consistent line of research suggests that a state of excessive exhaustion ensuing from long-term psychological strain is associated with elevated PAI-1. Therefore, an antifibrinolytic effect could help explain the observation that profound feelings of fatigue may precede an acute myocardial infarction.

Physiological Mechanisms

The pathophysiological underpinnings of the link between chronic stress and hemostatic changes are far from clear, though gene regulation, the SNS, and the HPA axis could all be involved. This seems particularly true in terms of PAI-1. In accordance with the observed decrease in PAI-1 with chronic stress,

restraint stress and injection of nonselective β -adrenergic substances in animals (i.e., epinephrine, isoprenaline) both resulted in upregulation of PAI-1 mRNA (Table 2) with a concomitant increase of PAI-1 activity in tissue homogenates. Moreover, homozygote carriers of the 5G allele of the PAI-1 4G/5G gene polymorphism who were exhausted had higher PAI-1 levels than homozygote 5G allele carriers who were not exhausted. In contrast, homozygote 4G carriers and heterozygote 4G/5G carriers did not differ in their PAI-1 levels in relation to their state of exhaustion.

When controlling for a whole range of possible confounders, greater overnight catecholamine secretion predicted higher morning levels of fibrinogen and D-dimer, while overnight cortisol excretion was not independently related to morning PAI-1 levels in a working population. However, research on the role of the HPA axis and endogenous cortisol activity on hemostasis in situations of chronic stress is too scarce to make a definite statement. Notably, patients with Cushing's disease, which is characterized by high production of endogenous cortisol, have an increased risk of thrombosis. In addition, subjects who received exogenous glucocorticoids either experimentally or as treatment manifested a hypercoagulable state.

Conclusions and Future Directions

More than a century of research on stress effects on hemostasis strongly suggests that, in response to acute stress, healthy individuals show a hypercoagulable state that is physiological and that has served the human species to enhance the odds of surviving fight-and-flight situations. However, this evolutionary benefit could be harmful today in an environment characterized by comparably longer lasting psychological stressors than those encountered in ancient times when humans either were killed or could escape. Daily hassles experienced in a rapidly changing society, years of marital stress, and job strain, as well as becoming a caregiver for a loved one, may elicit repetitive and sustained hypercoagulability that has lost its protective nature, thereby contributing to atherosclerosis and eventually myocardial infarction.

There is good evidence to assume that, of the stress-mediating systems, it is the sympathomedullary system that plays a major role in hemostasis regulation. However, data on the role of the HPA axis are rare, and the effect of the parasympathetic nervous system on hemostasis has not been explored. Although there is preliminary evidence that the brain transforms perceived stress into a physiological stress response resulting in rapid hemostatic activation further downstream in the peripheral blood and gene

expression of hemostasis molecules, much research needs to be done to better elucidate these pathways. Also, we lack prospective studies investigating whether increased stress procoagulant reactivity has any impact on hard cardiovascular endpoints later in life. Often in the same large cohort, researchers reported that both hemostasis factors and stress predicted cardiovascular endpoints. However, none of these studies has investigated an additive or even multiplicative effect of stress and hemostasis on endpoints. If stress interacts with hypercoagulability in predicting cardiovascular disease, carefully conducted intervention studies on effects of stress management in its broadest sense on hemostatic function seem warranted. We could learn from these studies whether individuals with hypercoagulability exceeding its physiological magnitude could profit from, e.g., cognitive-behavioral stress management for better cardiovascular health.

Glossary

<i>Capsid</i>	The protein coat or shell that contains the nucleic acid genome of the virus particle.
<i>Capsomeres</i>	The individual morphological units (or sides) on the surface of the capsid.
<i>Envelope</i>	The lipid-containing outer membrane that surrounds the entire virus particle. The envelope arises from budding of

Icosohedron

Latent infection

Nucleocapsid

mature herpesvirus particles through the nuclear membrane.

Geometric shape with 20 equal sides or capsomeres (similar to a soccer ball). The herpesvirus capsid is an icosohedron.

When the virus persists in a quiescent (occult or cryptic) form most of the time with very little viral replicative activity. Herpesviruses are characterized by intermittent flare-ups of clinical disease.

Includes the capsid and the enclosed nucleic acid.

Introduction

The Herpesviridae represent a large group of viruses that are pathogenic for many vertebrates. To date, there are more than 130 identified herpesviruses, nine of which are classified as human herpesviruses. These include herpes simplex virus type 1 (HSV-1), HSV-2, human cytomegalovirus (HCMV), varicella-zoster virus (VZV), Epstein–Barr virus (EBV), and human herpesviruses 6A, 6B, 7, and 8. The name herpesvirus is derived from the Greek word *herpein*, which means

to creep. Such a name is quite appropriate, as this family of viruses is characterized by chronic, latent, and recurrent infections that appear to creep or crawl across the skin.

The pattern of infection with a herpesvirus depends on the portal of entry, and the site of viral replication is restricted by the surface proteins expressed by each species of virus. The herpesvirus family members cause a range of diseases, including infectious mononucleosis, chicken pox, shingles, gingivostomatitis (i.e., fever blisters and cold sores), genital herpes, and Kaposi's sarcoma. The severity of disease is chiefly dependent upon the immune status of the host. For example, in newborns or in immunocompromised adults, infection by HSV can be severe, resulting in encephalitis and possibly death. In contrast, healthy adults resolve the primary infection, and the virus becomes latent. In fact, several members of the herpesvirus family cause lifelong infections in humans that are characterized by periods of quiescence interrupted by reactivation and expression of clinical symptoms.

The type of cell in which a herpesvirus can become latent is specific to each herpesvirus. For HSV, the development of latency means that virions reside quietly in neural tissues without causing disease. In contrast, EBV establishes latency in B lymphocytes. In each case, periodic reactivation of the latent virus is frequently accompanied by clinical symptoms, production of infectious virus, and the development of herpetic lesions.

Virology

Characteristic Structure

Herpesviruses are large DNA viruses that share similar architectural details; they are morphologically indistinguishable from one another. Each member has a double-stranded DNA genome arranged in what has been described as a toroid core; in such a core, the DNA is spooled around a cylinder of proteins. The herpesvirus's toroid core is encapsulated within an icosahedral capsid. The capsid is composed of 162 capsomeres and is itself packaged within a lipid envelope. This envelope is formed from the nuclear membrane of an infected cell from which progeny viruses bud. Within this nuclear-lipid envelope are virus-encoded glycoproteins, or spikes, about 8 nm long. An additional feature of the herpesvirus family is a tegument, which is an amorphous, asymmetrical structure located between the capsid and envelope. The entire virion measures 120–200 nm, and the naked capsid is approximately 100 nm in diameter.

Characteristic Genome

The genome of herpesviruses is double-stranded linear DNA ranging from 120 to 250 kilobase pairs. The variation in size of the DNA genome among herpesvirus family members is due to a characteristic arrangement of their DNA sequences. Their genomes have terminal and internal repeat sequences that are bounded by a unique long (UL) and a unique short (US) region. These repeats allow some members of the family to undergo genomic rearrangement of their unique regions, giving rise to different genomic isomers. In addition, because of the high incidence of rearrangement, spontaneous deletions occur, and defective viral particles are common. Within the herpesvirus family, there is little DNA homology among the different species, with a few notable exceptions to this generality. Specifically, HSV types 1 and 2 share 50% sequence homology and herpesvirus 6 and 7 share 30–50% homology. However, because of the low homology among the herpesviruses, digestion of the genome with restriction endonucleases will yield a characteristic fragment pattern specific for each family member. This allows for rapid epidemiologic tracing of a given strain.

The genome of the typical herpesvirus is large and encodes for at least 100 different proteins, many of which (>35) are structural in nature. Additionally, all herpesviruses encode for a number of virus-specific enzymes that are involved in nucleic acid metabolism. These can include DNA polymerase, thymidine kinase, dUTPase, ribonucleotide reductase, helicase, and primase. It is important to note that none of these enzymes are packaged within the mature virus particle. They are expressed only during replication within the host cell.

Subclassification

More than 130 different herpesviruses have been identified, including nine human isolates. The herpesviruses are subdivided into three subclasses without regard to DNA sequence homology. Assignment to one of the three subfamilies, the alpha-, beta- and gammaherpesviruses, is based on biological properties, with emphasis given to host-range restriction and cellular tropism.

Alphaherpesviruses Alphaherpesviruses have a broad host range; they replicate rapidly in many types of cells. Although these are highly lytic viruses, members of this subclass can establish latency in neurons and glial cells. This group includes human HSV-1 and HSV-2, human VZV, and bovine herpesvirus type 1 (BHV-1).

Betaherpesviruses Betaherpesviruses have a restricted host range and grow slowly in tissue culture. Infection typically causes cells to enlarge, which is termed cytomegalia. These members can establish latency in hematopoietic progenitor cells and can cause persistent infections of epithelial and glandular cells. This group includes human and murine cytomegaloviruses (CMV), human herpesvirus 6, and human herpesvirus 7.

Gammaherpesviruses Gammaherpesviruses have a restricted host range. These viruses can replicate in epithelial cells and establish long-term latency in lymphocytes. In addition, some of these viruses can transform or immortalize their host cell. This group includes EBV and Kaposi's sarcoma-associated human herpesvirus (also called human herpesvirus type 8).

Virus Replication

Viruses are obligate intracellular parasites; as such, members of the Herpesviridae family must enter a host cell to undergo replication. Entry is a multistep process beginning with weak association of the virus envelope with the sugar moieties of cell membrane-associated proteoglycans (i.e., heparan sulfate and chondroitin sulfate). The second step of entry involves specific binding of the virus to a surface receptor. For example, EBV recognizes complement receptor 2 (CD21 or CR2) and HLA class II molecules. Human cytomegalovirus recognizes β_2 -microglobulin, while HSV-1 binds to a member of the tumor necrosis factor/nerve growth factor receptor family. In addition to these common receptors, other glycoproteins have also been implicated in herpesvirus recognition of host target cells, and the group of receptors has been termed herpes virus entry mediators (HVEMs). Distribution of HVEMs determines the tropism of herpesvirus for specific cell types. After binding, the virus enters the host cell by fusion with the cell membrane. After entry, the viral envelope remains part of the cell's plasma membrane, but the capsid is transported through the cytoplasm to a nuclear pore. At the pore, the DNA is released from the capsid through the pore and into the nucleus. Once inside the nucleus, the viral DNA immediately circularizes.

Expression of the viral genome is tightly regulated and sequentially ordered in a cascade fashion. Immediate-early genes are expressed, yielding alpha proteins (alpha proteins are those that are produced in the absence of prior virus gene transcription). The alpha genes contain promoters that are recognized by the host cell's own transcription factors and are, therefore, turned on as soon as the viral DNA enters the nucleus of the cell. During a productive herpesvirus infection, the host cell's enzymes are hijacked

for the good of the virus. For example, herpesviruses are dependent upon the host cell's RNA polymerase II for all viral gene transcription. Even though the cell's own enzymes are used by the virus during replication/infection, normal cellular DNA and protein synthesis virtually stop as viral replication begins. Synthesis of the immediate-early alpha proteins promotes the expression of the next set of genes, or early genes, which are translated into beta proteins.

Beta proteins are those that are expressed before DNA replication begins but require alpha gene expression. Synthesis of the beta proteins represents the telltale sign that viral DNA synthesis has begun. It is believed that the beta proteins include the enzymes that are required to replicate the herpesvirus genome (i.e., DNA polymerase, thymidine kinase, dUTPase, ribonucleotide reductase, helicase, and primase). Because it circularizes when it enters the nucleus, herpesvirus DNA is synthesized by a rolling circle or concatametric mechanism that appears seemingly endless. The length of the replication cycle varies from about 18 h for herpes simplex virus to over 70 h for cytomegalovirus.

As viral DNA replication begins, late transcripts are produced that give rise to gamma proteins (gamma proteins are those that are expressed after DNA synthesis). While many of the alpha and beta proteins are enzymes or DNA-binding proteins, the gamma proteins are structural in nature and are the proteins of the tegument, toroid core, capsid, and envelope. In other words, synthesis of the gamma proteins is necessary for assembly of infectious virus progeny. Of interest, the virus's capsid is assembled before the newly synthesized viral DNA is inserted. This occurs in the cell nucleus. After encapsidation (i.e., DNA insertion into the capsid), maturation of infectious progeny occurs by budding of nucleocapsids through the inner nuclear membrane. Enveloped viral particles are then released from the cell through the plasma membrane by a poorly defined mechanism. The host cell that produces infectious progeny does not survive.

Overview of Diseases Caused by the Herpesviridae

As there are over 130 different types of herpesviruses, it is not surprising that they cause a wide variety of diseases. As their subclassification into alpha-, beta-, and gammaherpesviruses suggests, primary infection and possible latency may involve different cell types and present a widely different set of symptoms and clinical disease.

Herpes simplex viruses Herpes simplex viruses (HSV) are extremely widespread in the human population and exhibit an ability to replicate in many host

tissues. They also infect other animals. There are two main forms of the herpes simplex viruses, human herpes viruses (HHV)-1 and -2, which are also known as HSV-1 and HSV-2. Both viruses grow rapidly and are extremely cytolytic. Typically, these viruses infect epithelial cells found in mucosal tissue and establish latent infections in peripheral neurons. HSV-1 has been classically associated with oropharyngeal lesions characterized by recurrent fever blisters. HSV-1 is spread by contact, usually involving infected saliva. HSV-2 has been associated with recurrent genital herpes and is usually transmitted sexually or from mother to neonate during vaginal birth. Both viruses can cause neurologic disease, with HSV-1 being the leading cause of sporadic encephalitis in the United States. Both HSV-1 and HSV-2 can cause severe primary infections in newborns. Latent infection followed by recurrent disease is the hallmark of these viruses. HSV-1 and HSV-2 reside in latently infected ganglia in a nonreplicating state with only a few viral genes being expressed; infectious virus cannot be isolated during latency. Persistence of the viral genome within a latently infected cell lasts for the lifetime of the host. Following a reactivating stimulus, the virus follows axons back to the peripheral site and replication proceeds in the epithelial cells. Spontaneous reactivation occurs despite HSV-specific immunity. More than 80% of the human population harbors HSV-1 in a latent form, but only a small percentage experience reactivation. Neither the cellular nor the molecular basis for reactivation is completely understood.

Varicella-zoster virus Varicella-zoster virus (VZV or human herpesvirus 3) is highly contagious and is a very common virus. Like the HSVs, VZV is an alphaherpesvirus. The typical route of infection for VZV is the mucosa of the upper respiratory tract. After primary replication in the mucosal epithelium, the virus enters the circulation and eventually localizes to the skin, where it causes two distinct syndromes. Upon primary infection, usually in children, it causes chicken pox (also called varicella), which is characterized clinically by a generalized vesicular eruption of the skin and mucous membranes. However, VZV subsequently establishes a latent infection, and upon reactivation, the virus causes shingles (also called zoster). Shingles is a sporadic, incapacitating disease of adults or immunocompromised individuals that is clinically characterized by a rash limited in distribution to the skin innervated by a single sensory ganglion. The lesions are similar to varicella.

Epstein-Barr virus Epstein-Barr virus (EBV or human herpesvirus 4) causes infectious mononucleosis

and is latent in most adults. EBV is commonly transmitted by infected saliva (hence the nickname the kissing disease). Primary infection involves epithelial cells of the oropharynx and parotid gland. Viral shedding occurs for weeks to months after infection. Following replication in epithelial cells, EBV infects B cells and quickly becomes latent. Latent EBV is a factor in the development of nasopharyngeal carcinoma, Burkitt's lymphoma, and other lymphoproliferative disorders in immunocompromised individuals. As it has been known for years that cells in tissue culture could be immortalized by EBV, we now realize that EBV is the prototypic gammaherpesvirus and is oncogenic in humans.

Cytomegalovirus Cytomegalovirus (CMV or human herpesvirus 5) infects respiratory epithelial cells or epithelial cells within salivary glands or the kidneys. CMV is believed to infect a majority of the human population worldwide, often without symptoms of overt disease. However, CMV infection causes congenital defects and mental retardation in more than 5000 infants in the United States per year. CMV is the largest herpesvirus, with a genome of approximately 240–250 kilobase pairs. Infection is characterized by massive enlargement of infected cells. Human CMV is the prototypical betaherpesvirus. Primary CMV infections in immunocompromised hosts are more severe than in normal hosts. Therefore, organ transplant recipients on immunosuppressive therapy and individuals with AIDS are predisposed to life-threatening infections by CMV.

Human herpesvirus 6 and human herpesvirus 7 Human herpesvirus 6 (HHV-6) and human herpesvirus 7 (HHV-7) were first recognized in 1986 and 1990, respectively. Both viruses were isolated from cultures of peripheral blood cells from patients with lymphoproliferative disorders involving T cells. Both have been classified as betaherpesviruses, as infection results in the formation of giant cells. HHV-6 and HHV-7 share significant sequence homology; however, they are antigenically and immunologically distinct. HHV-6 has been further subclassified into HHV-6A and HHV-6B based on distinct cellular tropism. Although HHV-6B is associated with roseola or exanthema subitum, HHV-6A and HHV-7 have not been associated with any known human disease.

Human herpesvirus 8 Human herpesvirus 8 is also known as Kaposi's sarcoma-associated herpesvirus; it was originally isolated in the mid-1990s from an AIDS patient with Kaposi's sarcoma. It is present in all forms of Kaposi's sarcoma, in primary B-cell effusion lymphomas, and in some forms of Castleman's

disease, each of which is more prevalent in immunocompromised patients. As each of these diseases is a form of cancer, HHV-8 has been characterized as a human tumor virus or gammaherpesvirus. HHV-8 expresses a number of cellular regulatory genes that the virus appears to have acquired from mammalian cells as a way of defeating host defense mechanisms.

B virus B virus is highly pathogenic for humans, although transmissibility of the virus from its normal host to humans is limited. Typically, B virus infects Old World monkeys and is enzootic in rhesus, cynomolgus, and other macaque monkeys. B virus infections in the natural host seldom cause overt disease, but latency is established and B virus is easily reactivated under stressful conditions. Infection of humans usually results from monkey bites and is associated with a high rate of mortality due to an acute, ascending myelitis and encephalomyelitis.

Immunobiology and Recurrent Disease

The course or natural history of a herpes viral infection is influenced by the site of viral entry and host defenses. Primary infection with a herpesvirus induces both innate and adaptive immune responses, which result in the termination of viral replication and cessation of clinical symptoms. However, unlike acute viral infections, in which a successful immune response leads to elimination of the virus, infection with herpesviruses frequently leads to latency and thus the opportunity for episodic recurrent disease.

Innate Immunity

All mammals are born with a genetically inherited resistance to infectious microbes termed innate or natural resistance. Expression of natural resistance does not require previous exposure to the viral antigen (as does the adaptive immune response). Recent evidence suggests that toll-like receptor (TLR)-2 and TLR-9, which are pattern recognition receptors, are the first to detect that the host has been infected with herpesvirus. Activation of the TLR pathway initiates the innate immune response, which is aimed at restricting the early spread and replication of the virus without regard to the type of virus. Macrophages, natural killer (NK) cells, and killer cells mediating antibody-dependent cellular cytotoxicity (ADCC) all have roles in restricting the early spread of the virus. Infection by members of the Herpesviridae family is also accompanied by the expression of genes encoding the type I interferons that impart resistance to uninfected cells surrounding an infected cell.

Adaptive Immunity

Most infections with members of the Herpesviridae result in the induction of virus-specific humoral (antibody) and cell-mediated immune responses. In contrast to innate immunity, it takes several days for these herpesvirus-specific adaptive immune responses to be generated. A primary infection with HSV, whether asymptomatic or symptomatic, results in the production of virus-specific antibodies (both binding and neutralizing). These antibodies play multiple roles in mediating resolution of the primary infection through direct viral neutralization and through lysis of the infected cells by an ADCC mechanism. Virus-specific T cells are also very important during infection; individuals with cell-mediated immunodeficiency suffer severe herpetic disease. Clearance of virus correlates with the presence of CD8⁺ T cells with virus-specific cytolytic activity. Immunological memory in both the B cell and T cell compartments also follows primary infection. However, neither the successful termination of virus replication during primary infection nor the establishment of immunological memory prevents reactivation of latent virus and the development of recurrent lesions.

Recurrent Disease

Whether the time to reactivation of latent virus is weeks to months (as is the case for HSV) or years to decades (as is the case for VZV), it is apparent that immune memory, which results from the resolution of a primary infection with these viruses, offers little protection against recurrent disease. The development of recrudescence lesions is a two-step process. The first step occurs at the cellular/molecular level and involves the regulation of viral and host transcription factors influencing the state of expression of the latent viral genome. The balance between positive and negative transcription factors determines whether the genome will be reactivated, and this process is mediated by numerous hormonal and growth factor signals. These signals may result from many different stimuli. Psychological stress, physical trauma, UV irradiation from a sunburn, and hormonal fluctuations of the menstrual cycle have all been associated with reactivation of latent virus.

The period of time in which the reactivated virus gets to replicate, and thus cause clinical symptoms, is immunologically limited (and represents the second step in the process). Healthy adults generally limit clinical symptoms during a recurrence to a couple of days or less, whereas individuals with diminished cell-mediated immunity, as seen in AIDS, often develop severe disease that lasts much longer.

Stress and Herpesvirus Reactivation

The capacity of latent herpesviruses to reactivate and replicate is essential for completion of the viral life cycle. In the case of HSV-1 latency, reactivation of herpesvirus from ganglia results in the appearance of infectious virus at the site of the initial primary infection – typically the lips or gingiva. During the latent phase of any herpesvirus infection, viral gene expression is highly restricted; latency-associated transcripts (LATs) are among the few viral genes routinely detected during latency. It is believed that LAT gene expression establishes and maintains latency as mutations in LAT or its promoter limit herpesvirus latency.

The factors that lead to reactivation are even less clear. The limited knowledge of the pathogenesis of herpesvirus reactivation has been generated from studies in laboratory animals including mice, guinea pigs, and rabbits. In these models, reactivating stimuli range from mechanical and pharmacological to immunological alterations of cells and surrounding tissues. It is known that the first viral genes that are expressed during reactivation are the herpesvirus alpha, or immediate-early, genes whose promoter regions contain sequences that are similar to the host's cells own promoters. Reactivating stimuli may drive transcription of cellular genes whose promoter regions share homology with the promoters of the herpesvirus alpha genes. Thus, it is thought that the alpha genes are transcribed by the host cell's own transcription factors. The virus is then triggered for reactivation.

It is commonly thought that physical and psychological stress may be contributing factors to reactivation of herpesvirus. The impact of psychological stress on immune function is well documented in the literature and supports the hypothesis that psychological stress can reactivate latent virus. Several studies have shown that reactivation of latent HSV infections is more frequent in individuals who experience traumatic life events such as the death of a family member, the stress of interpersonal problems, or work-related difficulties. Similar relationships between psychosocial stress and reactivation of other herpesviruses, including EBV and VZV, have also been reported. It is thought that the physiologic alterations that ensue during stress alter the cellular and molecular microenvironment and serve as reactivators of latent herpes infections.

In mammals, stressors typically activate a specific set of core stress responses, including the hypothalamic-pituitary-adrenal (HPA) axis and sympathetic nervous system (SNS). Activation of the HPA axis results in increases in glucocorticoids such as cortisol, while activation of the SNS results in increases in circulating and tissue levels of catecholamines such as epinephrine and norepinephrine. Each of these

alterations in host physiology has been linked to herpes reactivation. For example, a model for *in vivo* reactivation has been established in the rabbit eye. Epinephrine induces reactivation and shedding of mature infectious virus in the rabbit's tears. Glucocorticoids have also been implicated in reactivation. For example, cortisol can drive viral replication in primary cell cultures established from latently infected mouse trigeminal ganglia. Other experimental stressors (e.g., UV irradiation and transient hyperthermia), in a variety of animal models, can also cause recrudescence. However, the events that occur between stress and production of infectious herpesvirus are incompletely understood *in vivo*. Therefore, important biological knowledge remains unknown concerning reactivation.

Conclusion

The herpesviruses represent a diverse group of viruses that have evolved unique relationships with their hosts. Members of this viral group have been associated with diverse disease manifestations ranging from malignant transformation to latency and reactivation. Herpes infections occur from the cradle (neonatal HSV encephalitis) to the grave (shingles caused by reactivation of VZV in the later decades of life). They affect healthy individuals (e.g., CMV and mononucleosis) and immunodeficient individuals (e.g., human herpes virus type 8 which causes Kaposi's sarcoma in AIDS patients). Reactivation of the latent members of the herpesvirus family has been associated with multiple forms of stress (from physical stressors such as UV irradiation to psychological stress such as social conflict). Unfortunately, detailed knowledge of the molecular steps that trigger reactivation is lacking. Additional research is needed to gain a better understanding of these mechanisms and to help develop new prevention and treatment strategies that limit the replication, spread, and reactivation of the Herpesviridae.

Glossary

<i>Adenylyl cyclase</i>	A protein enzyme that when activated, for example by a G-protein, catalyzes the formation of an intracellular second-messenger molecule, cyclic adenosine monophosphate (cAMP).
<i>Cation channel</i>	A protein complex embedded in a cell's membrane that allows positively charged ions (e.g., Na ⁺ , K ⁺ , or Ca ²⁺) to pass through the membrane.
<i>G-proteins</i>	Guanine nucleotide (guanosine triphosphate, GTP, and guanosine diphosphate, GDP) binding proteins that associate with the intracellular portion of metabotropic receptors. G-protein alterations are the first step in a cascade of intracellular molecular changes triggered by neurotransmitter or hormone (ligand)

binding of metabotropic receptors at the membrane surface.

Neuropil

Brain region that consists primarily of neuronal processes (dendrites and axons) rather than neuronal cell bodies.

Spatial learning

Learning tasks in which optimal performance requires that the organism has learned the relative spatial relationship between objects in the environment. Spatial learning can be demonstrated by tasks in which the organism is able to select the most direct route to a location that it has been to before or, alternatively, by tasks in which the organism avoids revisiting places that it has been to before.

Overview

The hippocampal formation consists of the hippocampus and the closely associated dentate gyrus and subiculum. The hippocampal formation first attracted attention as a primitive region of the cortex that had an architecturally simple and orderly cellular organization. Strikingly detailed drawings of the microscopic organization of the hippocampal formation were provided by Ramón y Cajal in the late 1800s (**Figure 1**). This structure is dominated by the orderly alignment of two principal neuronal cell types: pyramidal cells and granule cells. Moreover, the principal cells of the hippocampal formation were found to be interconnected in such a way as to produce a simple intrinsic neurocircuit (the trisynaptic circuit). Interest in the hippocampal formation intensified when, based on human amnesic cases, it was found to be essential for the formation of new episodic memories and the acquisition of declarative facts. The intense study of the hippocampus has yielded the first characterized cellular functional response (long-term potentiation) believed to reflect the fundamental neuroplasticity underlying memory formation.

Figure 1 Drawing of a transverse section of the hippocampal formation highlighting the principal cells (e.g. B, D, G, h), their interconnections and presumed flow of neural impulses (arrows). Drawing by S. Ramón y Cajal, first published in 1911 (Ramón Y Cajal, *Histologie du système nerveux de l'Homme et des Vertébrés*. Paris: A. Maloine, 1911).

Subsequent study of the hippocampus has revealed a range of neuroplasticity phenomena that include dynamic changes in neuronal arborization, spine density, and synapse formation. Investigations in recent years have determined that neurogenesis is a routine feature of the adult dentate gyrus portion of the hippocampal formation. The characterization of these forms of hippocampal neuroplasticity has revolutionized recent neuroscience with the discovery that these neuroplastic changes are not restricted to critical developmental periods or recovery from brain injury but are a normal daily occurrence that persists throughout the life span.

Hippocampal Formation

Each of the components of the hippocampal formation is characterized by a single principal cell body layer sandwiched between two zones of neuropil, yielding a simplified version of cortex with only

three distinct layers. Extensively associated with the hippocampal formation, in terms of interconnections, is the adjacent six-layer entorhinal cortex. The hippocampus and its interleaved partner, the dentate gyrus, are two phylogenetically primitive cortical structures that are buried underneath the cortical mantle. In the human brain, these two enfolded sheets of rudimentary cortex are located within the temporal lobe (Figure 2). In the rodent brain, these structures extend more dorsal-anteriorly. The dorsal portion of the hippocampus is located immediately beneath the corpus callosum and has an anterior extension that approaches the septal region (Figure 3). The most caudal extent of the hippocampus is located in the ventral half of the caudal portion of rodent forebrain.

Dissected out of a rat brain, the combined dentate gyrus and hippocampus are somewhat banana-shaped. The longitudinal axis of this structure is often referred to as the septal-temporal axis of the hippocampus and dentate gyrus. The rostral approximately two-thirds of this structure is known as the dorsal hippocampus, and the caudal third is known as the ventral hippocampus. This structure is usually studied and depicted in the transverse/cross-sectional plane (Figure 3). The cellular organization of the hippocampus and dentate gyrus in mammals is remarkably consistent throughout its longitudinal extent. Recent anatomical studies, however, have demonstrated important differences in intrinsic and extrinsic connections within the dorsal and ventral hippocampus. These differences may have important functional significance. For example, there is some evidence that the dorsal hippocampus is more important for spatial learning and memory and that the ventral hippocampus selectively contributes to fear and other emotion-dependent behaviors and learning.

Laminar Organization of Dentate Gyrus and Hippocampus

The principal cell body layer of the hippocampal formation consists primarily of pyramidal cell bodies (hippocampus and subiculum) or granule cell bodies (dentate gyrus). The surrounding neuropil zones primarily comprise the proximal principal cells' dendrites and axons and the nerve terminals of extrinsic and intrinsic afferents. This laminar organization can be easily visualized when examining microscopically a transverse section of dentate gyrus and hippocampus (Figure 4a). Anatomists have subdivided the neuropil zones into different strata, based primarily on microscopic differences in the principal cell processes and the afferents and efferents present within each strata (Figure 4b). Note that each of these cortical

Figure 2 Relative location of hippocampal formation in human brain. The hippocampus and its interleaved partner, the dentate gyrus, reside beneath the cortical surface in the temporal lobe. (2000), *Memory, from mind to molecules*, New York: Scientific American Library.

sheets has been folded in half along its longitudinal axis. Therefore, when we view a cross section of this structure in the rat brain, the orderly aligned principal cell bodies form a C-shaped (hippocampus) or V-shaped (dentate gyrus) formation. As is evident when we view a horizontal cross section of ventral hippocampus, one edge of the hippocampal sheet is adjacent to the subiculum and entorhinal cortex (Figure 4c–d). The other edge of the hippocampal sheet is tucked inside the two folds of the dentate gyrus. The C-shaped formation of pyramidal cell bodies in the hippocampus is subdivided into three subfields based on morphological and interconnection distinctions. These subfields are designated

CA1, CA2, and CA3 (drawing on the Latin name for the hippocampus, *cornus Ammonus*, Ammon's horn). The CA3 region is adjacent to the dentate gyrus, and the CA1 region is adjacent to the subiculum. The smaller CA2 region has morphological, phenotypical, and connectional features that overlap with those of the CA3 and CA1 subregions, but in combination makes for a clearly distinct functional zone of cells. The granule cells in the dentate gyrus are relatively uniform throughout the V-shaped formation in terms of morphology, innervation, and projections. The two folds of dentate gyrus giving rise to the V-shaped formation are commonly referred to as the enclosed and free blades, or the

Figure 3 Relative location of hippocampal formation in rat brain. The hippocampus (including CA1 and CA3 subregions) and dentate gyrus (DG) form a banana-like structure with one end of the longitudinal axis located dorsal-rostrally near the septal (Se) region and the other end located ventral-caudally near the temporal (T) pole of the rat forebrain. suprpyramidal and infrapyramidal blades, of the dentate gyrus. Recent studies indicate that there are some clear differences in the relative afferent connections to the two blades of the dentate gyrus as well as discriminable tendencies in their projection to CA3 subregions. The intervening space between the two granule cell body-forming blades of the dentate gyrus is known as the hilus or polymorphic region of the dentate gyrus.

Lammellar Organization (Trisynaptic Circuit) of Dentate Gyrus and Hippocampus

Significantly, many of the intrahippocampal neural connections are maintained within a narrow cross-sectional area (lammellae). A simple unidirectional trisynaptic connection among the components of the hippocampal formation was deduced by Ramón y Cajal based on microscopic architecture (Figure 1). Around 1970, Andersen and colleagues provided electrophysiological evidence to support a predominantly lammellar organization of hippocampal function. This trisynaptic circuit (Figure 5a) begins with pyramidal neurons predominantly localized in layer II of entorhinal cortex. These cells project (perforant pathway) to both blades of the dentate gyrus

and form synapses on granule neuron dendrites (synapse 1). The granule neurons project (mossy fiber pathway) to CA3 and form synapses on the apical dendrite of CA3 pyramidal neurons within the stratum lucidum (synapse 2). A collateral axonal branch of the CA3 pyramidal neurons projects (Schaffer collateral) to CA1 and forms synapses on basilar and apical dendrites of CA1 pyramidal neurons (synapse 3). The primary output from this circuit, and from the hippocampus overall, proceeds from CA1 neurons to the adjacent subiculum and entorhinal cortex as well as to subcortical structures.

More recent investigations have determined that there is considerable divergence and convergence within the longitudinal plane of connections between the entorhinal cortex and the dentate gyrus and between CA3 pyramidal neurons and other CA3 and CA1 cells. Only the mossy fiber connections between the dentate gyrus and CA3 are predominantly restricted to a cross-sectional lammellae. Nevertheless, a fairly thin cross section of the dentate gyrus and hippocampus contains a number of intact cells of each trisynaptic circuit component. Therefore, the hippocampal formation is ideally suited for *ex vivo* study, in which a 250- to 500- μ m cross-section of this structure contains an electrophysiologically functional trisynaptic circuit. Consequently, with appropriate bath conditions for

neuronal survival, a cross-sectional brain slice of the hippocampus and dentate gyrus maintains many functional features of an intact hippocampal circuit. The *ex vivo* electrophysiological study of hippocampal slices has been instrumental in deciphering the cellular and molecular correlates of hippocampal-dependent learning (Figure 5b).

Principal Neurons

All the principal cells of the hippocampal formation (pyramidal and granule cells) are believed to be glutamatergic. Pyramidal cells have a distinctly pyramidal or tear-drop shape. Pyramidal cells in CA3 and CA2 have larger cell bodies (approximately 25 μm in diameter) than those in CA1 (approximately 15 μm in diameter) (Figure 6). Separate multibranching dendritic trees emerge from the apex and base of

each cell. The base of the cell is defined by the surface from which the axon emerges, and the separate dendritic trees are referred to as apical and basilar dendrites, with each cell having one or two apical dendrites and several basilar dendrites. All hippocampal pyramidal cells are aligned in the same orientation, with the apical dendritic trees radiating toward the center of the C-shaped semicircle of cells (filling the stratum radiatum). The basilar dendrites extend in the opposite direction (filling the stratum oriens). Hippocampal pyramidal cell axons penetrate the stratum oriens and travel as part of the alveus to distal hippocampal or subcortical targets.

Granule cells of the dentate gyrus have small spherical or ovoid-shaped cell bodies (approximately 8–15 μm in diameter). One moderately complex dendritic tree (filling the stratum moleculare) is attached to the pole of the cell opposite from where

Figure 5 Hippocampal-formation trisynaptic neural circuit. a, An intact unidirectional trisynaptic neural circuit in a 250- to 500- μ m transverse section of rat hippocampal formation (lamellae); b, *ex vivo* stimulation of a transverse slice of hippocampal formation placed in a chamber containing a solution of artificial cerebrospinal fluid to assess the electrophysiological activity in one component of the trisynaptic circuit. In (a) representative pyramidal cells (present in the entorhinal cortex, CA3, CA1, and subiculum) and a granule cell (in the dentate gyrus) that participate in the circuit are depicted. The three featured synapses of the circuit are numbered in the temporal order in which they are engaged by neural activity, starting with pyramidal neurons in the entorhinal cortex. In (b) a stimulating and recording electrode is applied to the tissue slice in order to assess electrophysiological activity within one component of the trisynaptic circuit. the axon emerges and projects. There is also a population of large-diameter cells in the hilus region of the dentate gyrus called mossy cells that also appear to be glutamatergic. These cells receive input from the mossy fibers and project back to the dentate gyrus granule cells. Interestingly, mossy cells preferentially project bilaterally to granule cells at other levels of the longitudinal axis than that in which they reside.

The dendritic trees of hippocampal formation principal cells are densely covered with bulbous spines

(Figure 6). The head of these spines form the postsynaptic site for much of the excitatory input to these cells. There are especially large prominent spines on CA3 neurons and mossy cells called thorny excrescences, which form the postsynaptic site for the mossy fiber input from the dentate gyrus. Inhibitory synapses, largely arising from γ -aminobutyric acid (GABA)ergic interneurons, are mostly localized to the soma, dendritic shafts, and axonal initial segments of the principal cells.

Figure 6 Hippocampal formation principal cells. Camera lucida tracings of representative CA1 and CA3 pyramidal cells in the hippocampus and a granule cell in the dentate gyrus (DG) from rat brain are shown. All three representative cells are oriented such that the axon emerges from the bottom of the cell body (an axon is clearly evident for the granule neuron). Multibranched apical (a) and basilar (b) dendritic trees are attached to the pyramidal cell body. The dendritic trees for the granule cell are attached to the upper portion of the cell body. A camera lucida tracing of an enlarged portion of a CA1 apical dendrite is also included. This tracing illustrates the dense presence of spines that cover the dendrites of these principal cells. Adapted from Gould, E., Woolley, C.S., Frankfurt, M., et al. (1990), *Gonadal steroids regulate dendritic spine density in hippocampal pyramidal cells in adulthood*. *Journal of Neuroscience* 10,1286–1291. © 1990 by the Society for Neuroscience.

Interneurons

There are various types of interneuron cell bodies scattered throughout all strata of the dentate gyrus and hippocampus. Most of these interneurons are presumed to be GABAergic, and they have been further categorized by the differential expression of various neuropeptides and calcium-binding proteins. Many of these interneurons have extensive axon collaterals and arborization that extend fairly long distances within both the longitudinal and transverse plane and form numerous synaptic contacts with principal cells. Although there are substantially fewer hippocampal interneurons than principal cells (probably totaling less than 1% of all hippocampal neurons), this pattern of connectivity allows them to have substantial effects on overall hippocampal function. Two of the better-characterized types of inhibitory interneurons are the basket cells and the chandelier or axoaxonic cells. The basket cells are so named because their multibranched axons form an extensive interwoven contact with the cell body of target pyramidal cells. The chandelier cells form strong synaptic contacts on the initial axonal segment of pyramidal cells. It should also be noted that there are many synaptic contacts between inhibitory interneurons as well as axodendritic contacts from principal cells. Thus, the

interneurons are interconnected in such a way as to mediate complex feedforward and feedback inhibition and disinhibition within the hippocampal formation.

Intrinsic and Extrinsic Neural Connections

A major source of neural input to the dentate gyrus, as previously described, is from the entorhinal cortex and constitutes the first component of the trisynaptic circuit. There are considerable reciprocal connections of the entorhinal cortex with other regions of neocortex, most notably the adjacent perirhinal cortex and the nearby postrhinal and piriform cortex. There are also substantial direct interconnections with the medial prefrontal, insular, and retrosplenial cortex. Thus, the entorhinal cortex is believed to provide the dentate gyrus and hippocampus with the rich multimodal sensory content of ongoing experience. In addition to the extensive input to the dentate gyrus, the entorhinal cortex also provides (via the temporal-ammonic pathway) direct monosynaptic parallel input to the CA3 region of the hippocampus, as well as direct input to CA1 pyramidal cells. Thus, both CA3 and CA1 neurons are in the position to integrate or compare direct and processed information from the entorhinal cortex. The projection of CA1 neurons back to the entorhinal cortex, either directly or via the subiculum, makes the entorhinal cortex the principal bidirectional interface between the hippocampal formation and various neocortical regions.

In addition to the trisynaptic circuit, there are extensive commissural and longitudinal associational connections within the hippocampus. The major source of these additional associational connections are provided by the non-Schaffer collateral branch of CA3 pyramidal cell axons, with additional contribution from CA2 pyramidal cells and mossy cells of the hilus.

There are other important neural inputs to the dentate gyrus and hippocampus from various populations of biogenic amine-containing neurons that may primarily modulate the general excitatory tone and neural synchronization within this structure. In addition, the CA1 region receives direct excitatory input from basal nuclei of the amygdala and midline nuclei of the thalamus. Interestingly, the amygdala input to the hippocampus is largely restricted to the ventral hippocampus.

The major output neurons of the hippocampal formation are pyramidal cells in CA1, subiculum, and deep layers of the entorhinal cortex. CA1 and subiculum pyramidal cells provide a large subcortical projection via the fornix to the septum and hypothalamus, with minor contribution from CA3 pyramidal cells. There are also strong direct connections of the

CA1 and subiculum with the medial prefrontal cortex. However, as previously indicated, there are more extensive indirect connections of the CA1 and subiculum with the prefrontal and other cortical areas via the entorhinal cortex.

Neurochemistry

Amino Acid Neurotransmitters

The excitatory neurotransmitter, glutamate, is released from hippocampal-formation principal cells and is therefore the neurotransmitter used by the perforant path, mossy fibers, and Schaffer collaterals. Glutamate receptor subtypes include the ionotropic receptors (iGluRs), which directly gate cation channels and are named after the ligands that preferentially bind to them: *N*-methyl-D-aspartate (NMDA), α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA), and kainate. All the iGluRs are present in the excitatory pathways of the hippocampus. AMPA and kainate receptors mediate fast excitatory postsynaptic potentials (EPSPs), and NMDA receptors mediate slower EPSPs. All the iGluRs open Na^+ and K^+ channels. NMDA as well as some AMPA and kainate receptors are also permeable to Ca^{2+} . The NMDA receptor is unique in that channel permeability is both ligand- and voltage-dependent.

There is also a family of metabotropic glutamate receptors (mGluRs) that are coupled to guanine nucleotide-binding proteins (G-proteins). mGluRs have both pre- and postsynaptic localization and can coexist in the postsynaptic density with iGluRs. Postsynaptically, mGluR regulate synaptic transmission by stimulating specific second-messenger cascades and generating slow synaptic responses. When expressed presynaptically, mGluR activation can modulate transmitter release.

The inhibitory neurotransmitter GABA can also act on both ionotropic and metabotropic receptors. GABA_A receptors are ionotropic and gate ion channels that are permeable to the anion Cl^- . GABA also binds a metabotropic receptor, GABA_B, which is coupled to a G-protein that, when activated, opens K^+ channels. When expressed postsynaptically, GABA_B receptor activation leads to a slow hyperpolarization. When expressed presynaptically, GABA_B receptor activation reduces neurotransmitter release.

Biogenic Amines

The major cholinergic input to the hippocampus is from the medial septal nucleus. Acetylcholine (ACh), similar to glutamate and GABA, can act on both ionotropic (nicotinic receptors) and metabotropic (muscarinic) receptors, both of which are expressed

in the hippocampus. Nicotinic ACh receptors are ligand-gated ion channels that mediate fast excitatory transmission via an influx of Na^+ and Ca^{2+} . Nicotinic receptors are expressed on both excitatory and inhibitory interneurons in the hippocampus and can be expressed pre- and postsynaptically. Muscarinic receptors are very densely expressed in the hippocampus, and different subtypes are differentially expressed on specific populations of neurons: M_1/M_3 on principal cells and M_2/M_4 on interneurons. The actions of muscarinic receptor activation can be excitatory or inhibitory, depending on the type of G-protein to which the receptor is coupled: M_1/M_3 are coupled to G_q (which stimulates phospholipase C), and M_2/M_4 are coupled to $\text{G}_{i/o}$ (which can inhibit adenylyl cyclase or activate a K^+ channel). Muscarinic receptor activation potentiates NMDA receptor activity, probably by the activation of the M_1 subtype. M_2 can be expressed as autoreceptors on cholinergic terminals. Acetylcholine is also known to regulate the release of dopamine, serotonin, and neuropeptides by the activation of presynaptic nicotinic and muscarinic receptors.

Cholinergic neurons that project to the hippocampus from the medial septal nucleus and the nucleus of the diagonal band of Broca contribute to the synchronous discharge of principal cells reflected by the prominent theta frequency hippocampal electroencephalograph (EEG). Theta is observed both during voluntary movement (Type 1, 8–12 Hz) and during alert immobility (Type 2, 4–6 Hz), although only Type 2 theta is sensitive to cholinergic manipulations.

Dopamine afferent terminals are observed in the ventral subiculum, in all strata of CA1, in the stratum oriens of CA3, and in the hilus of the dentate gyrus. The source of hippocampal dopamine comes from the midbrain ventral tegmentum and substantia nigra and there is some evidence for different populations of dopaminergic cells innervating dorsal and ventral hippocampal formations. Dopamine receptors comprise two types, D1-like (D1 and D5) and D2-like (D2, D3, and D4), and all are metabotropic. D5 is the most prominent D1-like receptor in the hippocampus and is coupled to G_s (which stimulates adenylyl cyclase). D5 receptors are expressed on pyramidal cells and can enhance NMDA- and AMPA-mediated currents. Dopamine D4 is the most prominent D2-like receptor in the hippocampus. D4 receptors are densely expressed on pyramidal neurons in CA1, on granule cells in the dentate gyrus, and on GABA interneurons. D4 receptors are coupled to $\text{G}_{i/o}$ and decrease NMDA-mediated excitatory transmission.

Norepinephrine innervation of the hippocampus arises primarily from the locus ceruleus, and the hippocampus contains one of the highest densities

of norepinephrine-containing terminals in the brain. Receptors for norepinephrine (adrenergic receptors) have been divided into two classes: α and β , which are further subdivided based on the specific G-proteins to which they are coupled. β -adrenergic receptors are coupled to G_s , while α_1 types are coupled to G_q and α_2 types to G_i . Electrical stimulation of the locus ceruleus produces an inhibition of hippocampal pyramidal neuron firing, followed by a transient increase in firing. The inhibition appears to be mediated by α_2 and the excitation by β receptors.

Serotonin (5HT) input to the hippocampus derives almost exclusively from the median raphe nucleus. Serotonin receptors in the hippocampus are preferentially expressed on calbindin-positive GABA interneurons, and the specific subtypes expressed include 5HT_{1A}, which is coupled to $G_{i/o}$; 5HT_{2A}, which is coupled to G_q ; and 5HT₃. The 5HT₃ receptor is an ionotropic receptor, the activation of which opens a nonspecific cation channel, resulting in fast depolarization. The activation of 5HT₃ receptors can thus inhibit the firing of pyramidal neurons by a GABA interneuron-mediated mechanism. There are also autoreceptors of the 5HT_{1B/D} subtype on serotonergic terminals that inhibit the release of serotonin. Intracellular recording studies show that the most prominent effect of serotonin application to the hippocampus is hyperpolarization of pyramidal neurons caused by an increase in K^+ conductance.

Histamine projections arise from the tuberomammillary nucleus of the hypothalamus. Histamine H₂ receptors are dense in CA1 and CA3 and are primarily located on pyramidal cell dendrites, but are also found on granule cells in the dentate gyrus. H₂ receptors are coupled positively to adenylyl cyclase, and the activation of these receptors causes strong excitation. Histamine H₁ receptors are mostly found in CA3, where their activation causes hyperpolarization. The H₁ receptor is coupled to stimulation of phospholipase C via $G_{q/11}$. H₃ receptors are also inhibitory (coupled to $G_{i/o}$) and are located on perforant path terminals in the dentate gyrus, where their activation can suppress glutamate secretion.

Other Neuromodulators

The hippocampus is rich in other neuromodulators, including neuropeptides, growth factors, cytokines, and endocannabinoids as well as their receptors. Neuropeptides are typically coreleased with classical neurotransmitters. Neuropeptides expressed in hippocampal neurons include cholecystokinin, somatostatin, neuropeptide Y, leptin, galanin, corticotropin releasing hormone, and the opioid peptides β -endorphin, enkephalin, and dynorphin. Receptors for the

gonadal and adrenal steroid hormones and thyroid hormone are also expressed in the hippocampus. Growth factors that are abundant in the hippocampus include brain-derived growth factor (BDGF), nerve growth factor (NGF) and fibroblast growth factor (FGF). Growth factors perform neurotrophic and neuroprotective functions and are critically involved in development and neuroplasticity. Cytokines regulate intercellular communication, including glial-to-neuronal and immune-to-neuronal communication. Cytokine ligands and their receptors found in the hippocampus include interleukin-1, tumor necrosis factor, and fractalkine. Eicosanoids are metabolites of arachidonic acid, which is derived from dietary linoleic acid. Several of the eicosanoids, including anandamide (arachidonylethanolamine) and arachidonylglycerol, are known as endocannabinoids because they act on the cannabinoid receptor CB1. High levels of CB1 expression are found throughout the hippocampus.

Neuroplasticity

Long-term potentiation (LTP) reflects a cellular model of learning and memory, first described in rabbit hippocampus in 1973. LTP is induced by applying a brief high-frequency electrical stimulus to an excitatory synaptic pathway, such as the hippocampal Schaffer collateral pathway, the perforant pathway, or the mossy fiber pathway (Figure 5b). For periods of hours (*in vitro*) to weeks (*in vivo*) after this conditioning stimulus, a test stimulus can subsequently provoke an increased synaptic response that is 50–200% above baseline. In the Schaffer collateral–CA1 synapse and the perforant path–dentate gyrus synapse, LTP is dependent on the activation of the NMDA receptor and subsequent Ca^{2+} influx (associative LTP), whereas in the mossy fiber–CA3 synapse, LTP appears to be dependent on kainate receptors (nonassociative LTP).

LTP has four basic characteristics that resemble features of learning and memory:

1. Temporal specificity: the presynaptic cell must fire before the postsynaptic cell.
2. Cooperativity: many synapses must be active to induce LTP.
3. Associativity: a strong input can induce potentiation at a weakly activated, adjacent synapse on the same postsynaptic cell.
4. Input specificity: potentiation is only induced at the synapses that received the conditioning stimulation.

In contrast to the potentiation caused by brief high-frequency stimulation, prolonged low-frequency stimulation of a pathway induces a long-term depression

(LTD) of the synaptic response to a test stimulus. Like the typical LTP found in most pathways (but not the mossy fiber pathway), LTD is also dependent on the activation of the NMDA receptor. It is thought that different patterns of Ca^{2+} influx produced during LTP and LTD induction determine the differential responses to these stimuli; high-frequency stimulation results in a large Ca^{2+} elevation and activation of the Ca^{2+} /calmodulin-dependent protein kinase (CaMK) cascade, whereas the smaller but more prolonged Ca^{2+} elevation produced by low-frequency stimulation leads to activation of a phosphatase cascade.

Hippocampal Function

The hippocampal formation appears to play a uniquely pivotal role in the brain's ability to form rapid and long-lasting associations between environmental stimuli in a way that allows for the learning of new concrete and abstract factual information (declarative memory) and detailed recall and recognition of events and places (episodic memory). The hippocampus in rodents appears to have an especially important role in learning the spatial configuration of places. Many CA1 and CA3 pyramidal cells behave as place cells; on initial exposure to a new environment, these cells acquire within several minutes the ability to increase their neuronal firing rate whenever the rat returns to a particular place in that environment.

The role of the hippocampus in stress response is less clear. As part of the limbic system, the involvement of the hippocampus in the generation of a stress state has often been presumed, but its anatomical neighbor, the amygdala, appears to play a much more important role than the hippocampus in this process. The cells of the hippocampus, however, appear to be especially sensitive to the effects of various stressors, perhaps in part due to their high expression of adrenal steroid receptors. Although the hippocampus may not be directly involved in the generation of a stress state, in the rat its more ventral regions contribute regulatory influences on hypothalamic-pituitary-adrenal (HPA) axis activity. Whether the primate hippocampus also has direct modulatory effects on the HPA axis remains to be determined.

Patch clamp recording

electrical activity, (i.e., the neurotransmitter response).

A method in which a very tight seal between an electrode and the cell membrane is established, allowing the recording of currents through single ion channels. If the membrane patch under the electrode is disrupted, the recording of potentials or currents over the whole cell is possible.

Mechanism of Corticosteroid Action

Targets for Corticosteroid Action

Changes in Network Properties

Cellular Effects after Chronic Hypo- or Hypercorticism

Glossary

<i>Extracellular recording</i>	A method for recording of electrical activity on the outside of neurons; often applied <i>in vivo</i> when recording the collective response of a group of neurons to the stimulation of afferents (i.e., the field response).
<i>Hippocampal slice</i>	A transversal slice of the hippocampal formation (~350 μm thick) kept alive <i>ex vivo</i> , in which the main synaptic pathways are still intact.
<i>Intracellular recording</i>	A method for recording of electrical activity in which the cell is impaled with a sharp electrode; generally used to record the potential or resistance over the entire membrane and changes thereof in the presence of neurotransmitters.
<i>Ion currents</i>	Ion fluxes over the neuronal membrane through specific ion channels. The activation of many of these channels depends on the membrane potential. In addition, some channels become inactive in a voltage-dependent manner.
<i>Long-term potentiation (LTP)</i>	Prolonged strengthening of synaptic contacts by patterned stimulation of afferent fibers; thought to play an important role in memory processes.
<i>Long-term depression (LTD)</i>	Prolonged weakening of synaptic contacts by patterned stimulation of afferent fibers; thought to play an important role in memory processes.
<i>Neurotransmitter response</i>	Neurotransmitters change the electrical properties of neurons either through activation of ligand-gated ion channels or G-protein-coupled receptors, which, via the intermediate effects of G-proteins and/or second messengers, act on a specific type of ion channel. Electrophysiological methods record only the final change in

Corticosteroid hormones affect cellular and network properties in the hippocampus in a slow but persistent manner. The nature of the effects depends on the relative participation of mineralocorticoid and glucocorticoid receptors.

Mechanism of Corticosteroid Action

Corticosteroid hormones, which are secreted from the adrenal gland in particularly high amounts after stress, enter the brain and bind to specific receptors. Two main types of receptors have been recognized: the high-affinity mineralocorticoid receptor (MR) and the lower-affinity glucocorticoid receptor (GR). Both receptor types are expressed abundantly in the hippocampal formation. In fact, most principal neurons in the hippocampal subfields ([Figure 1a](#)) coexpress the two receptor types. This has raised the question of how the activation of the two corticosteroid receptor types affects cellular properties in the hippocampus. One of the premises of initial studies was that the activation of MRs may affect hippocampal cell properties in a different way than GR activation. This has proven to be correct.

For neurons that coexpress MRs and GRs, the relative participation of the two receptor types in cellular effects depends on several factors. First, the relative amounts of the two receptor types are important. Even within the hippocampus, the amounts vary among the different subfields. For instance, pyramidal neurons in the CA1 region and granule cells in the dentate gyrus (see [Figure 1a](#)) express high amounts of both MRs and GRs. Pyramidal neurons in the CA3 region, however, have relatively low amounts of the GR. Second, the affinity of the receptor for the natural ligand, in combination with the availability of the ligand, plays an important role. The bio-availability in the hippocampus is not only determined by adrenal release of corticosterone, but also by factors such as the passage over membranes in which p-glycoproteins play a major role as well as the presence of converting

Figure 1 Corticosteroid effects on hippocampal cells. a, Representation of a hippocampal slice showing the main cellular subfields and the synaptic contacts between these subfields; b, Gene-mediated actions of corticosteroid hormones affecting the properties of hippocampal cells, aiming at various targets: ion channels, ionotropic receptors, G-protein-coupled receptors, and ion pumps. Intracellular corticosteroid receptors affect gene transcription either as homodimers binding directly to specific sequences in responsive genes or as monomers interacting with other transcription factors. CA1, cornus ammoni 1; CA3, cornus ammoni 3; DG, dentate gyrus; TF, transcription factor.

enzymes such as 11β -hydroxysteroid dehydrogenase. Low levels of the ligand activate MRs extensively due to their high affinity, whereas the lower-affinity GRs are only partly occupied. GRs are fully activated only when corticosteroid levels are very high. These two factors are not static entities but are prone to regulation, for example, during prolonged periods of exposure to stress.

Once corticosteroids are bound to their receptor, the steroid-receptor complex dissociates from attached proteins and translocates to the nuclear compartment. Rapid cellular effects of corticosteroids that are not gene-mediated have recently been described in hippocampus, but are not discussed here. Classically, it was thought that all gene-mediated corticosteroid actions, including those in the brain, involve binding of receptor homodimers to hormone response elements in the DNA (Figure 1b). Indeed, all functional effects studied so far in hippocampal cells appear to require DNA-binding of GR homodimers. However, molecular investigations – including microarray surveys in the hippocampus – indicate that effects can also take place via the interactions of steroid receptor monomers with other transcription factors. A third possible mode of action, via the heterodimerization of MR and GR molecules, has been suggested based on studies in transfected cells in which (among other things) protein–protein interactions were examined. It is still undecided whether MR–GR heterodimers play a major role in the development of corticosteroid actions in the hippocampus.

Over the past years, much more has become known about the genes that form a target for corticosteroid action in the hippocampus, as surveyed with serial

analysis of gene expression, microarrays, and single-cell RNA amplification of material from identified hippocampal cells. Thus, MR and GR activation each leads to altered expression of some 70–100 genes, of which roughly 50% was found to be upregulated and one-third were responsive to both receptor types. The hormone coordinates the expression of genes underlying aspects of energy metabolism, cell adhesion, synaptic transmission, oxidative stress, neurogenesis, cell cycle and structural plasticity. These transcriptional effects are likely to underlie cellular changes that have been observed, although the entire pathway has not yet been resolved for any of these. The functional data are in line with the molecular observations and indicate too that steroid-responsive genes may be involved in very diverse aspects of cellular function, such as cell structure and growth, energy metabolism, and membrane properties involved in signal transduction. Part of these cellular effects are summarized next.

Targets for Corticosteroid Action

Ion Channels

Under resting conditions, (passive) membrane properties of hippocampal CA1 and CA3 pyramidal cells are not affected by corticosteroid hormones. However, when the membrane potential of the cells is shifted from its resting level toward more depolarized or hyperpolarized levels (e.g., in response to a neurotransmitter), clear corticosteroid effects can be observed. These effects are generally slow in their onset and very persistent, which is in line with a gene-mediated mechanism of action. Patch clamp

and intracellular studies have shown that some, although not all, of the ionic conductances in hippocampal cells are modulated by MR or GR activation. This underlines that the hormone actions are pleiotropic but nevertheless show a distinct degree of selectivity.

Three types of ion conductances have been investigated with regard to corticosteroid sensitivity: potassium (K^+), sodium (Na^+), and calcium (Ca^{2+}). Of these, voltage-dependent Ca^{2+} conductances are clearly most sensitive to corticosteroid receptor activation. It was found that low levels of corticosteroids resulting in a predominant MR activation are associated with small Ca^{2+} currents. If activation of GRs occurs in addition to MRs (e.g., after stress exposure) this results in an increased amplitude of Ca^{2+} currents compared to the situation in which mostly MRs are occupied. Several types of Ca^{2+} channels contribute to the overall Ca^{2+} currents in hippocampal cells. The steroids affect at least L-type Ca^{2+} channels, which cause the sustained current seen with large depolarizations of the cell, such as happen during an action potential. Only the amplitude of the currents and not the kinetic properties or voltage dependency is altered by corticosteroid treatment. Interestingly, in the absence of corticosterone, Ca^{2+} current amplitudes are also large, pointing to a U-shaped corticosteroid dose-dependency (see Figure 2). These data indicate that MR activation is necessary to retain Ca^{2+} currents within certain limits (a situation that is preferable for a neuron), whereas GR activation in addition to MR activation increases the Ca^{2+} influx into the hippocampal cells.

Steroid modulation of Ca^{2+} influx indirectly affects the slow Ca^{2+} -dependent K^+ conductance, which is extremely sensitive to the intracellular Ca^{2+} concentration. This conductance is slowly activated when neurons are depolarized for a considerable period of time (>100 ms) and causes accommodation of the firing frequency during depolarization; because the channels are also slowly deactivated, a lingering after-hyperpolarization (AHP) of the membrane is seen after the depolarizing influence is terminated. Both accommodation and AHP suppress the transmission of excitatory input to the hippocampal cells. In agreement with the small Ca^{2+} influx seen with predominant activation of MRs, it was found that accommodation and AHP under those conditions are relatively small, which promotes the transmission of excitatory input. With additional GR activation, accommodation and AHP are increased, leading to a temporary suppression of excitatory signals. Thus, hippocampal CA1 neurons in which mostly MRs are activated effectively transmit excitatory signals without being exposed to large intracellular Ca^{2+} levels. The large Ca^{2+} influx seen with additional

Figure 2 Many hippocampal cell properties, such as calcium currents, are large in the absence of adrenal steroids (adrenalectomy, ADX) or when both corticosteroid receptor types are extensively activated and are small with predominant MR activation. This results in a U-shaped corticosteroid dose-dependency, similar to what has been found for the potency to induce long-term depression versus long-term potentiation in the hippocampus. The relative MR and GR activation is indicated below the dose-response curve. Cellular responses associated with predominant MR occupation induce a situation of stability and resistance to degeneration. Additional GR activation (e.g., after a moderate stress) generally results in a temporary suppression of hippocampal cell activity, in agreement with the adaptive and normalizing role of this receptor in the stress response. The instability linked to GR activation can become deleterious when GR activation occurs concurrently with other challenging situations for the tissue, such as ischemia. Under these conditions, cellular vulnerability is increased if the relative GR to MR activation is high.

GR activation is normally restrained because Ca -dependent K^+ conductances prevent large-scale depolarization. However, when GR activation is associated with extensive depolarization of neurons, such as occurs during epileptic or ischemic insults, cells are at high risk of being exposed to very high Ca^{2+} levels. This may partly explain why hippocampal cells show a more profound loss of function and integrity after hypoxia-ischemia or epileptic seizures when corticosteroid levels are persistently elevated.

The K^+ and Na^+ conductances that were investigated appeared to be far less sensitive to corticosteroid receptor activation. Relatively minor effects were observed on the properties of the inwardly rectifying K^+ conductance I_h and on the fast, tetrodotoxin (TTX)-sensitive Na^+ conductance. Other K^+ conductances, such as the delayed rectifier or transient A current, showed no steroid dependency at all in the hippocampus. Although the effects on voltage-dependent Na^+ and K^+ conductances are

thus relatively small, they could still result in an altered shape of the action potential.

Neurotransmitter Responses

Based on chemical structure, three classes of neurotransmitters are recognized that affect the cellular function of hippocampal cells: amino acids, biogenic amines, and neuropeptides. Of these, the responses to biogenic amines appear to be most sensitive to corticosteroid receptor activation. Corticosteroid effects on amino acid-mediated transmission seem to be diverse and only partly gene-mediated. Neuropeptide actions have largely not been investigated in this respect.

The responses to serotonin (5-hydroxytryptamine, 5-HT) are strongly modulated by corticosteroid receptor activation. Serotonin can bind to several types of receptors on CA1 pyramidal neurons, including the 5-HT_{1A} receptor. The activation of this receptor leads, through G-protein-coupling, to the opening of K⁺ channels, which results in a hyperpolarization of the membrane. With intracellular recording, it was found that the 5-HT_{1A} receptor-mediated hyperpolarization is small under conditions of predominant MR activation. This may be due to a MR-dependent downregulation of 5-HT_{1A} receptor mRNA expression, as was observed in the dentate gyrus and in some studies also in the CA1 region. The activation of GRs in addition to MRs (e.g., after exposure to a physical stressor) induces large 5-HT_{1A} receptor-mediated responses. The molecular mechanism underlying these large responses is unclear because 5-HT_{1A} receptor expression and binding are not increased after GR activation. Potential targets for steroid modulation downstream of the 5-HT_{1A} receptor are probably also not modulated because steroid actions on the G-protein function or the K⁺ channel opened by the G-proteins cannot explain the changes in 5-HT_{1A} response. In addition to modulation of 5-HT_{1A} receptor-mediated responses, corticosteroids also affect responses or expression of 5-HT₄ and 5-HT₇ receptors.

Depolarizing responses mediated via muscarinic acetylcholine receptors appear to have a similar steroid dependency. Because both serotonergic and cholinergic responses are relatively large in the absence of corticosteroid hormones, there seems to be a U-shaped dose-dependency for the transmitter responses, as in the case of Ca²⁺ conductances (see [Figure 2](#)). This may signify the existence of a common denominator underlying all these steroid effects. It is possible that corticosteroid receptor activation results in the altered activity of kinases or phosphatases, which affect several membrane components in a comparable way through posttranslational modifications. This does not exclude the development of steroid

actions aiming at specific genes. This is supported by the observation that responses to norepinephrine, mediated by β 1-adrenoceptors, show an inverse linear steroid dose-dependency rather than the U-shape.

Whereas the steroid modulation of biogenic amine responses is slow in onset, persistent, and requires *de novo* protein synthesis, steroid effects on amino acid-mediated responses seem to have different features. This was mostly investigated by examining the steroid modulation of synaptically evoked responses in the CA1 hippocampal region. The stimulation of Schaffer/commissural fibers in this region leads to a subsequent activation of glutamatergic AMPA and NMDA receptors. It was found that the administration of very high amounts of corticosterone, resulting in concomitant MR and GR occupancy, suppresses field responses mediated by glutamate receptors. With these very high doses of corticosterone a rapid onset of effects is seen and the effects are very prominent when extracellular Ca²⁺ concentrations are high. Moreover, the steroid effects are particularly evident after the repeated stimulation of the afferent pathway. The data suggest that under these circumstances energy-dependent processes in the signal transduction and cellular integrity may be impaired. When glutamate transmission is recorded under more physiological conditions (i.e., comparable to the design used to study effects on ion currents and aminergic responses), a slow GR-mediated enhancement rather than impairment of the responsiveness to synaptic stimulation becomes apparent.

Inhibitory responses mediated by GABA_A receptors are affected only by extreme (and probably physiologically not relevant) doses of corticosterone. GABA_B receptor-mediated responses were found to be stable with predominant MR activation, but declined rapidly with repeated stimulation both in the absence of steroids and in the presence of very high amounts of corticosterone.

Changes in Network Properties

The corticosteroid effects on the properties of individual hippocampal cells or small groups of cells clearly alter the function of hippocampal networks in which these cells participate. In addition, corticosteroid hormones could change network properties that depend critically on the connections and associative contacts between cells in a network.

Examples of processes that depend both on the characteristics of individual hippocampal cells and on the connections between cells are LTP and LTD. The former refers to the situation in which the high-frequency stimulation of afferents results in a prolonged strengthening of synaptic contacts. The fact

that LTP is induced rapidly in hippocampal subfields, persists for hours to days, and involves associativity of inputs has led to the hypothesis that LTP may be the neurobiological substrate for learning and memory, although a direct link is still disputed. Stimulating hippocampal pathways at a lower frequency can lead to LTD, the weakening of synaptic contacts. The processes of LTP and LTD each require specific intracellular signaling cascades, phosphorylation targets, and Ca^{2+} levels. In nonstressed animals, LTP can be induced easily with high-frequency stimulation, whereas homosynaptic LTD is relatively hard to obtain.

Many studies over the past decade have demonstrated that MR and GR activation largely affect the likelihood to evoke LTP and LTD. Both in the dentate gyrus and in the CA1 region, conditions that result in the near-complete activation of MRs and only partial activation of GRs are associated with a very efficient induction and maintenance of LTP. When GRs are activated extensively, it becomes hard to evoke LTP, whereas LTD induction is promoted. In the absence of corticosteroid hormones, LTP induction is also suppressed. The degree of potentiation therefore shows an inverted U-shaped steroid dose-dependency, which points to an underlying process that may be common to and perhaps evolve from the steroid actions on Ca^{2+} influx and responses to neurotransmitters such as serotonin.

These observations, generally obtained by administering exogenous corticosterone or selective agonists or antagonists for the corticosteroid receptors, can be extended to behaviorally relevant situations. Thus, several studies have shown that the exposure of animals to stressors that are unpredictable and out of the context of a learning experience suppresses the likelihood of inducing LTP and instead allows the induction of LTD. Even less extreme situations, such as the subjection of animals to a novel environment out of the context of a learning experience, led to a similar suppression of LTP and promotion of LTD. Stress effects on LTP and LTD are sometimes quite rapid in onset and not always associated with extensive changes in GR activation. This indicates that a shift in the likelihood of evoking LTP depends not only on the actual MR–GR occupation but also on other factors, such as the recent history of the postsynaptic cells, which may be influenced by other stress hormones as well, such as norepinephrine and corticotropin releasing hormone (CRH). In the intact organism, the effects of corticosteroids on synaptic plasticity are also determined by the degree to which multiple brain regions, such as the prefrontal cortex and amygdala nuclei, are involved, which in turn depends on the nature of the stressor.

Cellular Effects after Chronic Hypo- or Hypercorticism

The corticosteroid effects on cellular properties and network function described previously, are generally observed over a period of several hours after a change in MR/GR occupation. It is therefore very likely (and this has indeed been demonstrated in several cases) that these effects on hippocampal function take place shortly after exposure to an acute stressful situation. Increased corticosterone levels after stress, resulting in GR activation on top of already activated MRs, evokes an array of effects, most of which temporarily suppress the transmittal of excitatory signals (see Table 1). These GR-mediated events may help restore hippocampal function following stress, which is in accordance with the normalizing and adaptive mode by which GRs participate in the stress response.

Although large variations in MR activation probably do not take place under physiological conditions, data nevertheless show that MRs play an important role in hippocampal function. First, MRs seem to be important for the full development of GR-mediated events (and vice versa). Second, MR activation is essential for maintaining a basal level of hippocampal activity (see Table 1). And MR activation is even a prerequisite for neuronal viability. This is most evident in granule cells of the dentate gyrus. Dentate granule cells proliferate from progenitor cells even in adulthood and after some time die through apoptosis. There is a continuous balance between the incorporation of newly formed cells and the removal of old cells. When rats are adrenalectomized, this balance is disturbed, so that 3 or more days after adrenalectomy proliferation is increased but also more cells

Table 1 Cellular effects observed with predominant MR activation or with concurrent MR and GR activation^a

	Excitability ↑	Excitability ↓
MR activation	Accommodation/AHP ↓ 5-HT _{1A} receptor response ↓ Glutamatergic response ↑ LTP ↑	Carbachol responses ↓
MR + GR activation	GABA _B response ↓ Glutamate release (?) ↑ Carbachol responses ↑	Accommodation/AHP ↑ 5-HT _{1A} receptor response ↑ β-Adrenergic response ↓ Glutamate response ↓ LTD ↑, LTP ↓

undergo apoptosis. In adrenalectomized rats undergoing apoptosis, the synaptic transmission as well as the plasticity between the entorhinal cortex and the dentate gyrus is impaired. The functional impairment most likely occurs prior to and independent of the change in cell turnover and may in fact form a trigger for an overall synaptic reorganization in the dentate. The impaired synaptic function, as well as the changes in cell turnover, can be prevented by treating animals with MR ligands. The fate of an individual cell also appears to be determined by its specific gene expression pattern. The data indicate that relatively young dentate cells can increase the expression of proteins that will help them survive, whereas older cells fail to do so, explaining why destabilizing factors such as enhanced calcium influx or impaired synaptic communication, seen in the absence of corticosterone, can become deleterious. Collectively, normal MR function in the dentate gyrus seems to be important in preserving the delicate balance between viability and cell death.

Although prolonged deprivation of corticosteroids is a threat for dentate granule cell survival, chronic overexposure of the hippocampus to corticosteroid hormones is also potentially harmful. Exposure of rats to 3 weeks of restraint stress causes atrophy of apical dendrites in CA3 pyramidal neurons. Under these conditions, both the presynaptic nerve terminals and the postsynaptic spine density in the CA3 area are altered. Chronic stress also decreases proliferation in the dentate gyrus and in fact may slow down the entire cell cycle for a considerable period of time, possibly by changing the expression of endogenous factors involved in the cell cycle. In addition to (or perhaps related to) the morphological effects, other hippocampal properties are also altered after chronic stress. Glutamate transmission is enhanced both in the CA3 area and dentate gyrus. Conversely, LTP is markedly impaired in all hippocampal subareas. Interestingly, 5-HT_{1A} receptor-mediated responses become gradually attenuated after chronic stress or prolonged overexposure to corticosterone. This may be one explanation for the increased risk of mood disturbances after prolonged hypercortisolemia.

The mechanisms underlying the changes in hippocampal morphology and cell turnover after chronic stress exposure are largely unknown. The observed enhancement in glutamate transmission may be a causative factor, but clearly sequential regulation of many gene targets, including genes encoding for corticosteroid receptors and chaperones, enzymes, structural proteins, cell cycle factors, and growth factors, in concert determines the outcome of the process. Understanding this sequence of events will

be one of the challenges for the future. It is already clear that the cellular actions induced by repeated overexposure to corticosterone are not a simple extrapolation of the effects seen after an acute rise in corticosteroid level. Also, in the hippocampus there is no evidence for steroid resistance – generally effects are strongest when chronic stress is combined with an acute rise in the level of corticosterone. Insight into these fundamental processes as well as the potential to intervene with pharmacological treatment (e.g., by applying antiglucocorticoids) will be essential for novel treatment strategies of stress-related disorders involving hippocampal dysfunction.

Hippocampal Regulation of Hypothalamic-Pituitary-Adrenal (HPA) Activity

Glucocorticoid Regulation of Hippocampal Activity

Chronic Stress and Hippocampal Function

Glucocorticoids and Hippocampal Function

Conclusions

Glossary

Feedback inhibition

A process whereby the end product of the system is able to inhibit the activity of higher order, stimulating events. In the case of the hypothalamic-pituitary-adrenal axis, the adrenal glucocorticoids inhibit corticotropin-releasing factor synthesis in hypothalamic neurons.

Plasticity

The ability of neurons to establish new contacts with other neurons through the formation of synaptic connections. The process can also refer to the strengthening of established connections.

Hippocampal Regulation of Hypothalamic-Pituitary-Adrenal (HPA) Activity

Under most conditions, the hypothalamic-pituitary-adrenal (HPA) axis lies under the dominion of specific releasing factors secreted by neurons located in paraventricular nucleus (PVN) of the hypothalamus, notably corticotropin-releasing factor (CRF) and arginine vasopressin (AVP). Neurons of the PVN project extensively to the portal capillary zone of the median eminence, furnishing a potent excitatory signal for the synthesis and release of adrenocorticotrophic hormone (ACTH) from the anterior pituitary, and thus the means by which neural activity associated with the stressor is transduced into endocrine signals. Elevated ACTH levels, in turn, increase the synthesis and release of glucocorticoids from the adrenal (in primates the primary glucocorticoid is cortisol, whereas in rodents it takes the form of corticosterone).

The responsivity of the HPA axis to stress is in part determined by the ability of the glucocorticoids to regulate ACTH release (i.e., glucocorticoid negative feedback). Circulating glucocorticoids act on pituitary and specific brain regions to inhibit the synthesis and secretion of releasing factors from hypothalamic neurons and pituitary ACTH. In addition to pituitary and hypothalamic sites, there is now considerable evidence of the importance of the limbic system, the hippocampus, and the front cortex in the regulation of HPA activity.

Circulating glucocorticoids bind with high affinity to two corticosteroid receptor subtypes: the mineralocorticoid receptors (MRs) and the glucocorticoid receptors (GRs). Both receptor subtypes have been implicated in mediating glucocorticoid feedback effects. Interestingly, ligand-activated MRs and GRs act as a common DNA-binding site (the corticosteroid receptor response element), but the receptors differ in their ability to interact with intracellular proteins (i.e., protein-protein actions).

Lesions to the hippocampus in the rat or the primate result in elevated corticosterone levels under basal and poststress conditions, whereas glucocorticoid implants into the hippocampus normalize ACTH levels in adrenalectomized rats. Hippocampectomized animals show a reduced suppression of HPA activity following exogenous glucocorticoid administration. Finally, hippocampectomy results in increased CRH mRNA levels in the parvocellular region of the PVN (a region that contains neurons whose axons terminate in the median eminence and increased portal concentrations of ACTH secretagogues). The negative feedback effects of glucocorticoids at the level of the hippocampus appear to involve both corticosteroid receptor subtypes. Implants of RU28318, an antagonist selective for the mineralocorticoid sites, and/or RU38486, an antagonist selective for the glucocorticoid site, increase basal and poststress HPA activity (i.e., antagonize endogenous glucocorticoid negative feedback). Levels of GR occupancy in the hippocampus and hypothalamus are correlated negatively with portal concentrations of CRH and AVP. Finally, both MR and GR agonists with selective antagonists underscore the state-dependent influence of these receptors. MR antagonists implanted into the hippocampus elevate basal as well as stress-induced HPA activity, whereas GR antagonists affect stress-induced activity. In humans, both mineralocorticoid and GR antagonists have been found to increase plasma ACTH levels, and, as in the rat, the effects of MR and GR blockade

depend on the time of day. These roles are consistent with corticosteroid receptor pharmacology, as modest basal steroid levels serve to occupy largely MRs. Dynamic variations in GR levels occur only under conditions of elevated steroid levels, such as with the circadian peak or during periods of stress.

Naturally occurring and experimentally induced variations in hippocampal corticosteroid receptor levels produce effects of HPA activity that are consistent with this formulation. In the rat, postnatal handling increases hippocampal GR but not MR expression, and the effect is largely unique to the hippocampus. Predictably, animals handled in early life show dampened stress-induced HPA activity as adults, whereas there is no effect on basal activity. Likewise, increased maternal licking/grooming during early life increases hippocampal GR expression, resulting in enhanced glucocorticoid negative feedback sensitivity, decreased hypothalamic CRF mRNA expression, and more modest HPA responses to stress. Lewis rats exhibit increased hippocampal MR levels and show lower basal and stress-induced activity in comparison to the parent Wistar strain. Thus, both MR and GR activation can potentially alter both basal and stress-induced HPA activity; under normal circumstances, the low corticosteroid levels prevailing under basal conditions selectively activate MRs. GR activation normally occurs during the peak in the circadian cycle or during periods of stress, and it is at this time that the GR influence on HPA activity is apparent.

Glucocorticoid Regulation of Hippocampal Activity

Glucocorticoids have been known for some time to regulate the excitability of hippocampal neurons, and more recent studies using models of long-term potentiation (LTP) have helped clarify the relevant mechanisms of action. LTP can be induced by the brief tetanic stimulation of glutaminergic afferents to either the CA1 or dentate gyrus region of the hippocampus and is defined by the enhanced synaptic response to subsequent stimulation. This LTP is thought to model the processes of synaptic plasticity that mediate learning. The magnitude of the hippocampal LTP response in the rat is decreased with adrenalectomy, and this effect is reversed with low levels of corticosterone replacement that affect largely MR occupancy. However, higher levels of corticosterone, which serve to occupy both MR and GR sites, reverse this effect, and with increasing GR activation, there is an even further suppression of LTP well beyond the effect of ADX, resulting in an inverted U-shaped relationship between circulating glucocorticoid levels and

hippocampal LTP. The mechanism underlying this effect involves the corticosteroid regulation of intracellular Ca concentrations. Following a prolonged sequence of stimulation, hippocampal neurons exhibit a slow, enduring afterhyperpolarization (AHP) that is mediated by a slow Ca-dependent K conductance, serving to decrease hippocampal excitability. Ca influx through voltage-gated channels, and thus the strength of AHP, is modest under conditions of MR occupancy and is increased substantially with the occupation of GRs. Elevated corticosterone levels increase mRNA levels for several Ca channels, whereas MR activation has the opposite effect.

There are also relevant corticosteroid effects on neurotransmitter systems. Glutaminergic transmission drives hippocampal LTP and is enhanced under conditions of MR activation and suppressed with increasing GR activation. Norepinephrine acts via cAMP-coupled β -adrenoreceptors to attenuate the magnitude of the AHP and thus enhance hippocampal excitability, an effect that is diminished under conditions of elevated corticosterone levels, which activate GRs. Serotonin (5-HT) acts via 5-HT_{1A} receptors to produce a hyperpolarization and thus a decrease in hippocampal excitability. This effect is enhanced through GR activation. Finally, GR activation can also serve to metabolically compromise the function of hippocampal neurons through effects on glucose transport.

These findings are consistent with the idea that hippocampal excitability and LTP formation are facilitated under conditions of low basal corticosterone levels that result in MR activation. As corticosterone levels rise, such as under conditions of stress, there is greater GR activation, which serves to increase AHP, dampen glutaminergic transmission, attenuate noradrenergic facilitation of excitability, and increase serotonergic inhibition. Taken together, these findings are consistent with the inverted U relationship between circulating corticosterone levels and hippocampal LTP. Importantly, steroid pharmacology is also consistent with the findings that stress impairs hippocampal LTP formation.

Chronic Stress and Hippocampal Function

Exposure to chronically elevated glucocorticoid levels further compromises hippocampal function to the point of endangering neuronal integrity and survival. The story again focuses, at least in part, on corticosteroid effects on Ca homeostasis. Chronic stress in rodents and primates produces a reversible regression of apical dendrites. The effect is mimicked by high

doses of corticosterone and is blocked by corticosterone synthesis inhibition or by Ca channel blockers. Interestingly, these effects parallel changes in the expression of a hippocampal-derived neurotrophic factor, brain-derived neurotrophic factor (BDNF). Chronic stress or chronically elevated corticosterone levels decrease BDNF mRNA expression as well as that for *trkB*, the BDNF receptor.

Elevated glucocorticoid levels compromise not only the maintenance of the existing synaptic form, but also synaptic sprouting. This finding is consistent with the GR-mediated effects on LTP, which appear to involve synaptic plasticity. Partial deafferentation in selected regions of the adult brain results in a sequence of compensatory events involving both the remaining afferent fibers and denervated dendrites, culminating in a reorganization of the circuitry in the denervated area. These events include sprouting of the remaining afferent fibers, restoration of spine density and length, and replacement of vacated synaptic contacts. One of the best examples of such reactive synaptogenesis occurs in the dentate gyrus of the hippocampus in animals following entorhinal cortex lesions. Entorhinal cortex lesions disrupt the perforant path, resulting in nearly 60% loss of synaptic input to the granule cells of the dentate gyrus. However, beginning as early as a few days after the lesion, new synapses are formed, and within 2 months virtually all the lost inputs are replaced. Following fimbria-fornix lesions, synaptic replacement occurs as a result of the growth of fibers from the adrenergic neurons in the superior cervical ganglion into the denervated region. In the case of entorhinal damage, the new synapses originate from the cholinergic cells of the medial septum, from glutaminergic commissural-associational pyramidal cells, and, to a lesser extent, from neurons of the contralateral entorhinal cortex.

Glucocorticoids suppress hippocampal sprouting in young animals in a dose-related manner. High glucocorticoid levels reduce hippocampal sprouting significantly following lesions of either the fimbria-fornix or the entorhinal cortex. This effect appears to be mediated by glucocorticoid effects on the expression of genes involved in synaptic repair, such as cellular receptor systems involved in cholesterol scavenging and microtubule-associated proteins.

The degree of glucocorticoid exposure appears to be a determinant of hippocampal pathology after neurological insult, as well as during the aging process. In humans, poststroke damage is correlated positively with circulating cortisol levels. In brief, Sapolsky's studies have shown that glucocorticoids endanger hippocampal neurons by (1) limiting the availability of energy substrates, thus rendering neurons metabolically compromised, and (2) increasing

extracellular glutamate concentrations by reducing glutamate uptake by glial cells. Both corticosteroid actions are GR mediated. These effects appear to be most apparent under conditions of insult associated with hyperexcitation and metabolic challenge. In contrast, MR activation appears to be neuroprotective under these same conditions.

Data from the laboratories of Sloviter and McEwen have illustrated another dimension to the corticosteroid regulation of neuronal survival in the hippocampus. In these studies, long-term adrenalectomized animals showed a profound decrease in neuron density in the dentate gyrus, a hippocampal subregion. In this case, the absence of glucocorticoid stimulation in adult animals resulted in neuron loss. Interestingly, the effects were observed uniquely in the granule cells of the dentate gyrus. Pyramidal cell density in Ammon's horn (CA1–CA4) was completely unaffected. In contrast, chronic exposure to elevated glucocorticoid levels results in the loss of pyramidal neurons in Ammon's horn, whereas the dentate is unaffected. Landfield's group reported that long-term adrenalectomized animals maintained under conditions of low corticosterone replacement showed no changes in neuron density in the dentate gyrus. The key here is the low level of corticosterone replacement. McEwen's group found that low levels of corticosterone or aldosterone replacement are sufficient to block the effects of adrenalectomy on neuron density in the dentate gyrus; both treatments selectively target the hippocampal MR. In contrast, Sapolsky's group showed that the loss of pyramidal neurons in Ammon's horn in the presence of elevated glucocorticoid levels is mediated by the GR. Thus, glucocorticoid potentiation of the neurotoxic effects of excitatory amino acids on hippocampal neurons is mimicked by RU28362, a GR agonist, and blocked by RU38486. In an interesting parallel, Meaney and Lupien showed that during the early postnatal period, an active period of hippocampal development, there are high, adult-like levels of MRs and very low levels of GRs. In essence, low levels of corticosteroid stimulation are necessary for the maintenance of hippocampal granule neurons, and chronically elevated glucocorticoid levels are hazardous for the integrity and survival of pyramidal neurons. The ideal state is one of tight titration around low basal glucocorticoid levels, an important argument for efficient glucocorticoid negative feedback.

Glucocorticoids and Hippocampal Function

Corticosteroid treatment has been known for some time to induce a reversible psychotic condition

(so-called steroid psychosis) in certain individuals. This condition also includes logical thinking. A dementia-like syndrome (including attentional deficits and memory impairments) occurs frequently in a group of patients given high doses of corticosteroids for disorders not related to the central nervous system and who did not show evidence of psychosis. These findings are consistent with studies of Cushing's patients, in which cortisol levels are elevated profoundly. Cushing's patients consistently show attentional deficits and memory impairments, and the magnitude of the impairments correlates with plasma cortisol levels. Interestingly, the older subjects (>45 years) were affected more seriously; these subjects showed significantly greater memory impairments than younger subjects. Importantly, these deficits were reversible; surgical intervention to correct the hypercortisolemic state resulted in normalized cortisol levels and improved cognitive performance.

In addition, cognitive impairments, including attentional deficits and verbal and visual memory impairments, are often associated with clinical depression and are correlated with increased cortisol levels. Again, both the increase in plasma cortisol and the magnitude of the cognitive disturbances are more severe in elderly patients, often resulting in a condition of so-called pseudodementia. Importantly, in hypercortisolemic patients (especially dexamethasone-resistant patients) the cognitive disturbances are more pronounced. Results showed that subjects who received hydrocortisone treatment presented an impaired performance in the declarative memory task but not in the nondeclarative memory task, thus suggesting that cortisol interacts with hippocampal neurons to induce cognitive deficits. Another study reported comparable deficits in declarative memory in response to higher cortisol levels associated with major stress.

Depression is also associated with hippocampal atrophy, and is commonly associated with increased cerebrospinal levels of CRF and adrenal hypertrophy, suggesting a degree of glucocorticoid feedback insensitivity. Considering the evidence for hippocampal atrophy in this propulsion, it is tempting to speculate on the potential involvement of the hippocampus dysfunction as a source of this feedback insensitivity and the hypercorticoid state. The problem is that the hippocampus can be seen as both victim and villain in this conspiracy. It is both a source of feedback regulation over HPA activity and a primary target for elevated glucocorticoid levels. It also appears to be a target for therapeutic intervention. Antidepressant drugs increase hippocampal expression of both MR and GR, enhance glucocorticoid negative feedback sensitivity, and reduce hypothalamic CRF expression.

Among aged rats, increased hippocampal GR levels are associated with enhanced feedback inhibition of HPA activity and reduced evidence of hippocampal aging.

While the results of the clinical studies have been largely correlative, there is considerable evidence for the idea that the exogenous administration of corticosteroids impairs cognitive function. The oral administration of 10 mg of hydrocortisone leads to a significant decrease in memory performance as tested 60 min after hydrocortisone intake. In this study, declarative and nondeclarative memory performance was measured in order to assess the influence of corticosteroids on the hippocampal formation process. The logic for the inclusion of this amnesic dissociation is due to the fact that studies report that the hippocampus is essential for a specific kind of memory, notably declarative, while it is not essential for nondeclarative memory. Declarative memory refers to the conscious or voluntary recollection of previous information, whereas nondeclarative memory refers to the fact that experience changes the facility for the recollection of previous information without affording conscious access to it (priming). Thus, this somewhat specialized role of the hippocampus serves as the basis for specific hypotheses regarding the effects of acute administration of corticosteroids on human cognition. The results showed that subjects who received hydrocortisone treatment presented an impaired performance in the declarative memory task but not in the nondeclarative memory task, thus suggesting that cortisol interacts with hippocampal neurons to induce cognitive deficits.

Although most of the effects of exogenous administration of glucocorticoids on human psychophysical and cognitive processing have been found using hydrocortisone as a compound, some other studies have used other compounds and reached different conclusions. Poor performance (errors of commission; incorrectly identifying distractors as targets) on verbal memory tasks occurs in normal volunteers following the administration of prednisone (80 mg/day for 5 days). The general cognitive deficit described in this study involved the relative inability to discriminate previously presented relevant information (target) from irrelevant information (distractors) in a test of recognition memory. The authors concluded that exogenous administration of corticosteroids may diminish the encoding of meaningful stimuli and impair selective attention (i.e., reducing the ability to discriminate relevant from irrelevant information).

It appears that medium-high levels of circulating glucocorticoids may first affect the process of selective attention, thus impairing further explicit acquisition of information, whereas high-very high levels

of circulating corticosteroids may affect explicit memory. This suggestion has been confirmed by a dose-response hydrocortisone infusion study in normal controls in which a 300 µg/kg/h infusion of hydrocortisone impaired selective attention capacity, whereas a 600 µg/kg/h infusion impaired both selective attention and explicit memory.

The results of these studies suggest that in humans, as in rodents, elevated glucocorticoids serve to compromise hippocampal function and promote cognitive impairments. This hypothesis was tested in a population of elderly, generally healthy human subjects in a study that examined cognitive function in relation to individual differences in HPA activity and hippocampal integrity. Basal cortisol levels were correlated inversely with impairments, including deficits in spatial learning and memory, and were associated with the degree of hippocampal loss. These findings are consistent with those using rodent populations. Prolonged exposure to elevated glucocorticoid levels can serve to compromise hippocampal integrity and certain forms of learning and memory. There is an impressive level of functional equivalence between the rodent and human model of hippocampal aging and the apparent role of corticosteroids in promotion degeneration.

Conclusions

The assumption drawn from earlier rodent studies is that all of this is entirely irreversible. However, more recent studies have emphasized the role of dendritic atrophy as a major component of the loss of hippocampal volume associated with a prolonged exposure to elevated corticosteroid levels. Neuron loss may be a more minor component of the earlier phases of hippocampal degeneration than was originally thought. Second, more recent studies have underscored the very dynamic effects of elevated circulating glucocorticoid levels on cognitive process, suggesting that attentional impairments that culminate in learning and memory deficits need not necessarily be seen as arising only under circumstances in which prolonged corticosteroid exposure has led to rampant structural damage. Rather, the processes by which glucocorticoids impair cognition can be dynamic.

The central question for human studies, then, is whether in at least some cases the functional impairments associated with elevated glucocorticoid exposure are reversible. Rodent studies suggest that stress-induced hippocampal atrophy is reversible. The critical question is whether it can be reversible in an elderly human population. As has so often been the case, the seminal experiment on this issue comes from the Landfield laboratory, which showed that the

effects of chronic stress on hippocampal function were more serious and enduring in older than in younger animals. It might well be that this scenario emerges from a conspiracy between the endangering effects of glucocorticoids against a background of aging, which involves a more limited level of trophic support and thus a decreased ability to repair the damage associated with the stressor. In our minds, the question of reversibility is critical.

Hiroshima Bombing, Stress Effects of

R J Lifton

Harvard Medical School and Cambridge Health Alliance,
Cambridge MA, USA

Published by Elsevier Inc.

I was recently told that a prominent Zen Buddhist leader in this country has made a vow to himself that, in any conversation he enters into, he must bring up the subject of nuclear threat. That includes – so the story goes – the most casual social conversations, talks with taxi drivers, brief exchanges with strangers, whatever. The vow did not sound strange to me. Without being quite aware of it, I had, in effect, made a similar, if much more modest, vow to myself: that in any public statement I make on nuclear threat, I will bring up the subject of Hiroshima.

My strong impulse is to convey to everyone Hiroshima's indelible impact upon me. And I also

have come to sense, as both psychiatrist and antinuclear activist, the special power of specific Hiroshima or Nagasaki images for those able to receive them. Images that extreme are best described in relatively quiet, understated tones that encourage reflection on our contemporary situation. The themes put forward in this article (originally from a chapter of mine in a book co-authored with Richard Falk, *Indefensible Weapons*) are meant to portray Hiroshima not as an event of the past, but as a source of necessary knowledge for the present and the future.

Those Hiroshima images continue their insistent claim on me: the searing details of survivors' experiences; the moving scenes, collective pain, and ultimate inadequacy of the 6 August day of commemoration; our own bittersweet family celebration, with a few Hiroshima friends, of our son's first birthday. Put most simply, the 6 months spent in Hiroshima in

1962 have formed in me a special constellation of truth that, when I am wise enough to draw upon it, informs everything I have to say about nuclear threat and much else.

I arrived in Hiroshima in the early spring of 1962. I intended no more than a brief visit. But very quickly I made a discovery that I found almost incomprehensible. It had been 17 years since the dropping of the first atomic weapon on an inhabited city – surely one of the tragic turning points in human history – and no one had studied the impact of that event. There had of course been research on the physical aftereffects of the bomb, and there had been brief commentaries here and there on the behavior of some of the survivors at the time of the bomb and afterward. But there had been no systematic examination of what had taken place in people's lives, of the psychological and social consequences of the bomb.

I came to a terrible, but I believe essentially accurate, rule of thumb: the more significant an event, the less likely it is to be studied. Again, there are reasons. One reason, certainly relevant to Hiroshima, has to do with the fear and pain the event arouses – the unacceptable images to which one must, as an investigator, expose oneself. To this anxiety and pain I can certainly attest.

But another source of avoidance is the threat posed to our traditional assumptions and conventional ways of going about our studies. We would rather avoid looking at events that, by their very nature, must change us and our relation to the world. We prefer to hold on to our presuppositions and habits of personal and professional function. And we may well sense that seriously studying such an event means being haunted by it from then on, taking on a lifelong burden of responsibility to it.

I was able to stay in Hiroshima and conduct interview research with people there over a 6-month period. The best way I know to describe a few of my findings that might be of use to us now is to look at the Hiroshima experience as taking place in four stages.

The first stage was the immersion in the sea of dead and near-dead at the time the bomb fell. This was the beginning of what I have called a permanent encounter with death. But it was not just death: it was grotesque and absurd death, which had no relationship to the life cycle as such. There was a sudden and absolute shift from normal existence to this overwhelming immersion in death.

Survivors recalled not only feeling that they themselves would soon die but experiencing the sense that *the whole world was dying*. For instance, a science professor who had been covered by falling debris and temporarily blinded remembered: "My body seemed all black. Everything seemed dark, dark all over.

Then I thought, 'The world is ending.'" And a Protestant minister, responding to scenes of mutilation and destruction he saw everywhere, told me: "The feeling I had was that everyone was dead. The whole city was destroyed. . . . I thought all of my family must be dead. It doesn't matter if I die. . . . I thought this was the end of Hiroshima, of Japan, of humankind." And a writer later recorded her impressions:

I just could not understand why our surroundings changed so greatly in one instant. . . . I thought it must have been something which had nothing to do with the war, the collapse of the earth, which was said to take place at the end of the world, which I had read about as a child. . . . There was a fearful silence, which made me feel that all people . . . were dead. (Lifton, 1982 [1967] pp. 22–23.)

As psychiatrists, we are accustomed to look upon imagery of the end of the world as a symptom of mental illness, usually paranoid psychosis. But here it may be said that this imagery is a more or less appropriate response to an extraordinary external event.

In referring to themselves and others at the time, survivors described themselves as "walking ghosts", or, as one man said of himself: "I was not really alive." People were literally uncertain about whether they were dead or alive, which was why I came to call my study of the event *Death in Life* (1968).

Indicative of the nature of the event is the extraordinary disparity in estimates of the number of people killed by the bomb. These vary from less than 70,000 to more than 250,000, with the City of Hiroshima estimating 200,000. These estimates depend on whom one counts and how one goes about counting, and can be subject at either end to various ideological and emotional influences. But the simple truth is that nobody really knows how many people have been killed by the Hiroshima bomb, and such was the confusion at the time that nobody will ever know.

The second stage was associated with what I call "invisible contamination". Within hours or days or weeks after the bomb fell, people – even some who had appeared to be untouched by the bomb – began to experience grotesque symptoms: severe diarrhea and weakness, ulceration of the mouth and gums with bleeding, bleeding from all of the body orifices and into the skin, high fever; extremely low white blood cell counts when these could be taken; and later, loss of scalp and body hair – the condition often following a progressive course until death. These were symptoms of acute radiation effects. People did not know that at the time, of course; and even surviving doctors thought it was some kind of strange epidemic. Ordinary people spoke of a mysterious "poison."

But the kind of terror experienced by survivors can be understood from the rumors that quickly spread among them. One rumor simply held that everyone in Hiroshima would be dead within a few months or a few years. The symbolic message here was: none can escape the poison; the epidemic is total – all shall die. But there was a second rumor, reported to me even more frequently and with greater emotion: the belief that trees, grass, and flowers would never again grow in Hiroshima; that from that day on, the city would be unable to sustain vegetation of any kind. The meaning here was that nature was drying up altogether. Life was being extinguished at its source – an ultimate form of desolation that not only encompassed human death but went beyond it.

These early symptoms were the first large-scale manifestation of the invisible contamination stemming from the atomic particles. The symptoms also gave rise to a special image in the minds of the people of Hiroshima – an image of a force that not only kills and destroys on a colossal scale but also leaves behind in the bodies of those exposed to it deadly influences that may emerge at any time and strike down their victims. That image has also made its way to the rest of us, however we have resisted it.

The third stage of Hiroshima survivors' encounter with death occurred not weeks or months but years after the bomb fell, with the discovery (beginning in 1948 and 1949) that various forms of leukemia were increasing in incidence among survivors sufficiently exposed to irradiation. That fatal malignancy of the blood-forming organs became the model for the relatively loose but highly significant term "A-bomb disease." Then, over decades, there have been increases in various forms of cancer – first thyroid cancer, and then cancer of the breast, lung, stomach, bone marrow, and other areas. Since the latent period for radiation-induced cancer can be quite long, and since for many forms it is still not known, the results are by no means in. Researchers are still learning about increases in different cancers, and the truth is that the incidence of virtually *any* form of cancer can be increased by exposure to radiation.

An additional array of harmful bodily influences have been either demonstrated, or are suspected, to be caused by radiation exposure – including impaired growth and development, premature aging, various blood diseases, endocrine and skin disorders, damage to the central nervous system, and a vague but persistently reported borderline condition of general weakness and debilitation. Again, the returns are not in. But on a chronic level of bodily concern, survivors have the feeling that the bomb can do anything, and that anything it does is likely to be fatal. Moreover,

there are endless situations in which neither survivors themselves nor the most astute physicians can say with any certainty where physical radiation effects end and psychological manifestations begin. There is always a "nagging doubt". For instance, I retain a vivid memory of a talk I had in Hiroshima with a distinguished physician who, despite injuries and radiation effects of his own, had at the time of the bomb courageously attempted to care for patients around him. He spoke in philosophical terms of the problem of radiation effects as one that "man cannot solve"; but when I asked him about general anxieties he smiled uneasily and spoke in a way that gave me the strong sense that a raw nerve had been exposed:

Yes, of course, people are anxious. Take my own case. If I am shaving in the morning and I should happen to cut myself very slightly, I dab the blood with a piece of paper – and then, when I notice that it has stopped flowing, I think to myself, 'Well, I guess I am all right.' (Lifton, 1982[1967] p. 54).

Nor does the matter end with one's own body or life. There is the fear that this invisible contamination will manifest itself in the next generation, because it is scientifically known that such abnormalities *can* be caused by radiation. There is medical controversy here about whether genetic abnormalities have occurred: they have not been convincingly demonstrated in studies on comparative populations, but abnormalities in the chromosomes of exposed survivors have been demonstrated. People, of course, retain profound anxiety about the possibility of transmitting this deadly taint to subsequent generations. For instance, when I revisited Hiroshima in 1980, people said to me: "Well, maybe the next generation is okay after all, but what about the third generation?" The fact is that, scientifically speaking, no one can assure them with certainty that subsequent generations will not be affected. Again, nobody knows. So there is no end point for possible damage, or for anxiety.

No wonder, then, that a number of survivors told me that they considered the dropping of the bomb to be a "big experiment" by the United States. It was a new weapon; its effects were unknown; American authorities wanted to see what those effects would be. Unfortunately, there is more than a kernel of truth in that claim, at least in its suggestion of one among several motivations. More important for us now is the idea that any use of nuclear warheads would still be, in a related sense, "experimental."

The fourth stage of the Hiroshima experience is its culmination in a lifelong identification with the dead – so extreme in many cases as to cause survivors to feel "as if dead" and to take on what I spoke of as

an “identity of the dead.” Hiroshima and Nagasaki survivors became, in their own eyes as well as in those of others, a tainted group, one whose collective identity was formed around precisely the continuous death immersion and the invisible contamination I have been discussing. The identity can include what we may think of as paradoxical guilt – the tendency of survivors to berate themselves inwardly for having remained alive while others died, and for not having been able to do more to save others or to combat the general evil at the time of the bomb. In connection with the latter, the sense of “failed enactment” (Lifton, 1983 [1979] p. 174) can have little to do with what was possible at the time or with what one actually did or did not do.

More than that, survivors underwent what can be called a second victimization in the form of significant discrimination in two fundamental areas of life: marriage and work. The “logic” of the discrimination was the awareness of potential marriage partners (or families and go-betweens involved in making marriage arrangements) and prospective employers that survivors are susceptible to aftereffects of the bomb, making them poor bets for marriage (and healthy children) and employment. But the deeper, often unconscious feeling about atomic bomb survivors was that they were death-tainted, that they were reminders of a fearful event people did not want to be reminded of, that they were “carriers,” so to speak, of the dreaded “A-bomb disease.”

At the end of my study of these events, I spoke of Hiroshima, together with Nagasaki, as a last chance, a nuclear catastrophe from which one could still learn. The bombs had been dropped, there was an “end of the world” in ways I have described, yet the world still exists. And precisely in this end-of-the-world quality of Hiroshima lie both its threat and its potential wisdom.

Is Hiroshima, then, our text? Certainly as our *only* text, it would be quite inadequate. We know well that what happened there could not really represent what would happen to people if our contemporary nuclear warheads were used. When the Hiroshima and Nagasaki bombs were dropped, they were the only two functional atomic bombs in the world. Now there are approximately 50,000 nuclear warheads, most of them having many times – some a 100 or a 1000 or more times – the destructive and contaminating (through radiation) power of those first “tiny” bombs. While those early bombs initiated a revolution in killing power, we may speak of another subsequent technological revolution of even greater dimensions in its magnification of that killing power. The scale of Hiroshima was difficult enough

to grasp; now the scale is again so radically altered that holding literally to Hiroshima images misleads us in the direction of extreme understatement.

Yet despite all that, Hiroshima and Nagasaki hold out important nuclear-age truths for us. The first of these is the *totality of destruction*. It has been pointed out that Tokyo and Dresden were decimated no less than was Hiroshima. But in Hiroshima it was one plane, one bomb, one city destroyed. And the result of that single bomb was incalculable death and suffering.

A second Hiroshima truth for us is that of the weapon’s *unending lethal influence*. Radiation effects were (and are) such that the experience has had no cutoff point. Survivors have the possibility of experiencing delayed but deadly radiation effects for the rest of their lives. That possibility extends to their children, to their children’s children, indefinitely into the future – over how many generations no one knows. And we have seen how the physical and psychological blend in relation to these continuing effects.

A third truth, really derived from the other two, has to do with Hiroshima and Nagasaki survivors’ identification of themselves as *victims of an ultimate weapon* – of a force that threatens to exterminate the species. This sense had considerable impact on Hiroshima survivors, sometimes creating in them an expectation of future nuclear destruction of all of humankind and most of the earth.

And there is still something more to be said about Hiroshima and Nagasaki regarding our perceptions of nuclear danger. The two cities convey to us a sense of *nuclear actuality*. The bombs were really used there. We can read, view, and, if we will allow ourselves, *feel* what happened to people in them. In the process we experience emotions such as awe, dread, and wonder (at the extent and nature of killing, maiming, and destruction) – emotions surely appropriate to our current nuclear threat. Such emotions can transform our intellectual and moral efforts against nuclear killing into a personal mission – one with profound ethical, spiritual, and sometimes religious overtones. Hiroshima, then, is indeed our text, even if in miniature.

The argument is sometimes extended to the point of claiming that this sense of nuclear actuality has prevented full-scale nuclear war; that, in the absence of the restraining influence of Hiroshima and Nagasaki, the United States and the Soviet Union would have by now embarked upon nuclear annihilation. The claim is difficult to evaluate; and while I feel some of its persuasiveness, I do not quite accept it. In any case, one must raise a countervailing

argument having to do with another dimension of Hiroshima and Nagasaki's nuclear actuality: namely, the legitimization of a nation's using atomic bombs on human populations under certain conditions (in this case, wartime). Once a thing has been done, it is psychologically and in a sense morally easier for it to be done again. That legitimization can then combine with an argument minimizing the effects of the Hiroshima bomb: the claim that one has unfortunately heard more than once from American leaders that Hiroshima's having been rebuilt as a city is evidence that one can fight and recover from a limited nuclear war.

Here I may say that part of Hiroshima's value as a text is in its contrasts with our current situation. One crucial contrast has to do with the existence of an outside world to help. Hiroshima could slowly recover from the bomb because there were intact people who came in from the outside and brought healing energies to the city. Help was erratic and slow in arriving, but it did become available: from nearby areas (including a few medical teams); from Japanese returning from former overseas possessions; and, to some extent, from the American Occupation. The groups converging on Hiroshima in many cases contributed more to the recovery of the city as such than to that of individual survivors (physically, mentally, or economically). But they made possible the city's revitalization and repopulation.

In Hiroshima there was a total breakdown of the social and communal structure – of the web of institutions and arrangements necessary to the function of any human group. But because of the existence and intervention of an intact outside world, that social breakdown could be temporary.

Given the number and power of our current nuclear warheads, can one reasonably assume that there will be an intact outside world to help? I do not think so.

Like any powerful text, Hiroshima must be read, absorbed, and recreated by each generation searching for its own truths.

Glossary

Acquired immuno-deficiency syndrome (AIDS)

A clinical state of severe immune compromise associated with HIV infection, characterized by opportunistic infections, malignant tumors (especially Kaposi sarcoma), or a CD4 lymphocyte count of less than 200.

CD4 cell

A specialized cell of the T portion of the immune system, also referred to as a helper T lymphocyte. This cell is responsible for maintaining immune competence and is one of the cells infected selectively with the HIV virus and destroyed as a consequence of viral replication. As the body's ability to

Human immunodeficiency virus (HIV)

replenish CD4 cells fails, the CD4 cell count number falls. This is one predictor of worsening disease.

One of a group of RNA-containing retroviruses, a specific causative agent of AIDS. Similar but distinct retroviruses appear to be fairly widely disseminated in nature and are responsible for such diverse illnesses as feline leukemia, a simian AIDS-like illness, and, rarely in humans, a T-cell lymphoma.

Perhaps no disease in history – ancient or modern – has evoked such strong emotional and societal reaction as has HIV infection. Certainly the major infectious pandemics – plague of the Middle Ages, cholera of Victorian England, and influenza of 1918 – have had higher attack rates and greater mortality. Those diseases, however, were limited geographically and communication was primitive, so news of their occurrence was not disseminated readily. In contrast, HIV is of worldwide occurrence, and its end result, AIDS, which was first described in the early 1980s, was initially associated with a very high mortality rate. HIV infection in an asymptomatic state may persist for years and may respond well to newer treatments, resulting in a chronic rather than acutely fatal disease. Because, however, of the earlier picture of AIDS, many people still equate HIV infection with a rapidly progressive fatal disease. Those perceptions result in stress for the HIV-infected individual, for his or her family and friends, and for noninfected individuals who have no behaviors to put them at risk but who harbor unrealistic fears concerning the transmission of HIV. Although fear seems to be the biggest psychological stress associated with HIV, the reactions to fear are varied and include anxiety, guilt, anger and frustration, denial, and obsessive disorders. Whereas most individuals are able to handle their stress in an appropriate way, a number of people have psychological, psychosomatic, or physiological symptoms as a result of the stress associated with HIV.

Stress Associated with Initial Testing for HIV

Many emotional factors go into the decision to obtain a test for HIV. The need to acknowledge behaviors that participants have engaged in, either episodically or consistently, but with which they are uncomfortable, influences the decision. Fear of rejection by family and peers, should they be infected, appears to be important. Incomplete knowledge of the significance of a positive test for HIV antibodies and feelings of hopelessness at being able to deal with the

consequences, such as loss of future, loss of employment, isolation, and pain, have been reported. Fears of discrimination in housing, in the workplace, and in society are not uncommon. Proponents of anonymous testing point out that anonymous testing has a tendency to allay those fears. It is clear that some individuals, having mustered their courage to get a test, do not return for results. Some members of the health community who feel an obligation to ensure that individuals, particularly those who test positive, are counseled appropriately argue against anonymous testing. The role of anonymous testing in reducing stress is thus not clear.

Some home-based HIV antibody test kits have been marketed. They have a certain appeal to individuals who are concerned with privacy to a degree that they will not otherwise be tested. If the test is positive, however, individuals may not seek or may delay appropriate medical care and avoid the necessity of dealing with the stresses that result from a positive test or deal with them in inappropriate ways.

The test that is performed most commonly involves sequential testing, first by enzyme-linked immunosorbent assay (ELISA) fluorescent antibody testing and a confirmatory chromatographic (western blot) test. Although the ELISA test may be performed quite rapidly (results usually available within a matter of 24 h), the western blot test takes somewhat longer and, in most laboratories, is not run with great frequency. Because it is important to have a confirmatory western blot test in every presumptively positive ELISA test and because there may be a considerable delay between obtaining blood and receiving results, there is tremendous anxiety during the interval between obtaining blood and obtaining the results. Although some practitioners report negative ELISA test results within 24 h to reduce that anxiety, the consequence is that people who do not have their test returned in a short period of time assume (although it is not necessarily true) that their test is positive. For that reason, most testing centers have an interval of 5–7 days between obtaining blood and giving results to all individuals. At the initial encounter, it is important that the counselor or phlebotomist take extra precautions, particularly in individuals at risk for HIV, to explain the consequences of a positive test and to explain the testing procedure to reduce fears about being tested.

Stress Associated with the Presence of HIV Disease

Individuals newly diagnosed with HIV infection go through the entire spectrum of behaviors from denial to bargaining to acceptance, as occurs in many

chronic and serious diseases. These reactions have been well documented by Kubler-Ross and are not covered here. The initial denial of infection may be a barrier to obtaining care because, on initially being told of the presence of HIV infection, many people do not hear or integrate further information at that session. Thus, many health practitioners bring patients back repeatedly over a short period of time and provide easy access to someone skilled in dealing with the emotional responses to a serious life-threatening disease. Many individuals rationalize that, although they are HIV infected, at least they do not have AIDS. This is a beneficial coping mechanism during early infection.

Soon after the detection of HIV infection, analyses of viral load and CD4 count are often obtained, and this information is used in predicting not only the course of the disease in an individual but also in arriving at a plan for therapeutic intervention. Individuals who have a normal CD4 count and low viral load, in most instances, progress very slowly over a period of years. This allows sufficient time to deal with the potential psychological issues that arise. Despite the best intentions of the practitioner, a small number of people have committed self-destructive acts, including suicide, on learning of HIV infection. It is important that practitioners be aware of these potential adverse affects and allow for continuing support. For individuals with more advanced disease who meet the case definition of AIDS and for people continuing to show deterioration of immune function, modern therapies have been able to reverse or at least stabilize the disease, and numerous authors have pointed out that a positive outlook is associated with longer survival and less frequent adverse consequences, including opportunistic infections.

Unfortunately, as the disease progresses, the HIV infection itself may be associated with symptoms that can be confused with psychosomatic illness. Paresthesia in the limbs, abdominal pain, dysphasia, and changes in mental outlook and functioning may all be a result of HIV infection, its therapy or secondary infections, or neoplastic disease. Similar symptoms, however, may result on a purely psychosomatic basis without any organic cause. The challenge to the practitioner is to discern which symptoms are organic and which are psychosomatic and to deal with them by appropriate intervention. Continuity of care from a multifaceted health-care team, including physicians, social workers, advocates, and individuals who are themselves HIV-infected, appears to be important in reducing the psychological stress associated with HIV.

Whereas the stress associated with HIV infection does not appear to vary with specific racial, ethnic, or behavioral factors, individuals who acquire this

infection through intravenous drug use have a separate set of stressors because of the drug use. This must be dealt with, either prior to or concomitantly with the evaluation and treatment of the HIV infection, to maximize outcome. It is clear that treating individuals who remain active drug users with potent antiviral medications is, more often than not, fraught with failure and the development of antiviral-resistant organisms. A small but well-documented group of individuals have expressed anger at finding they are HIV-infected and have purposely tried to infect other members of society with HIV. An even larger group of individuals do not understand the infectiousness of a nonsymptomatic transmissible disease and continue to expose others by persistent risk-taking behavior. On learning that they have been the source of infection for a loved one – a sexual partner or other close societal member – they experience significant guilt.

In addition to the psychological and psychosomatic stresses exhibited by individuals who are HIV-infected, physiological changes occur as a result of HIV infection. It is well documented that stress factors of a nonspecific type have a depressant effect on the immune system and may hasten the onset of symptomatic HIV disease and reduce life expectancy. Diurnal and stress-related changes in CD4 cell count and immune function are well known. There seems to be general agreement that a fall in natural killer cell numbers and CD8⁺ lymphocytes, both of which are present in high numbers with heightened immune activity, may occur in the presence of stress. Their mechanisms of falling are not clear but may be mediated by glucocorticoids and endorphins. A similar relationship of stress to the recurrence of herpes simplex viral infections is well described, hence the term cold sore or fever blister, the symptom that occurs when a concomitant stressful situation, including infection, causes the herpes virus to reactivate. Individuals addicted to crack or cocaine in any form, which seems to have a direct immunosuppressive effect, have a shortened life expectancy.

Stress for Family and Friends of HIV-Infected Individuals

The stresses imposed on the families of people who are HIV-infected are enormous. In many instances, because of the behaviors that resulted in the individuals becoming HIV-infected (particularly sex with members of the same gender and drug use), adult individuals who have moved some distance from the family will return home when the diagnosis of HIV is made or when symptomatic AIDS occurs. The family is often unaware of the behaviors that resulted in the individuals becoming HIV-infected,

and the family members are left with the consequences of dealing with or accepting behaviors with which they are not comfortable, as well as the grief from the potential fatal outcome of AIDS. Fears concerning acceptance by relatives, neighbors, and friends add to family stress.

In the case of parents, many are aged and unable to understand adult children and the behaviors that have led to HIV. The physical stress of moving individuals or caring for them when they become weakened from disease is physically and emotionally taxing. For many parents, dealing with the potential death of a child prior to their own demise is stressful, and they may require professional help. In areas where there is a high prevalence of HIV, children may be born HIV-infected as a result of pre- or perinatal transmission, and there are many well-documented instances of parents abandoning a child on learning that he or she is HIV-infected. This may add grief and guilt to the psychological stress of the family.

Stress for the Health-Care Team

As HIV infection becomes a much more chronic disease, a variety of stresses have become more apparent in the health-care team. The difficulties of dealing with a generally young population that is losing weight and becoming physically impaired and dependent have been severe. The short natural history of the infection in the past allowed people to cope with this deterioration in health. As the disease becomes chronic, health practitioners, particularly volunteers

and people who themselves may be at risk for HIV, have become increasingly frustrated with their inability to deal with the disease over the long term. In some instances, anger has replaced sympathy, leading to depression and other stress-related symptoms in the health-care team.

Glossary

<i>Holocaust</i>	The genocidal extermination of Jews during World War II.
<i>Stressors</i>	Noxious events that actually or potentially interfere with survival or the fulfillment of life's goals.
<i>Survivor</i>	A person who has lived through traumas, in this case the Holocaust.
<i>Trauma</i>	A state of irretrievable loss of a life promoting equilibrium.
<i>Traumatic stressors</i>	Situations that lead to trauma.

The experiences of the Holocaust have become a benchmark of suffering in stress and trauma situations. This was the result of the vast Nazi machinery of the day having directed all political, military, industrial, psychological, and bureaucratic resources to the unrelenting persecution and extinguishing of the culture, dignity, spirituality, and physical lives of all Jewish people. The extent and severity of the persecution resulted in every possible stress and trauma consequence occurring in large numbers and sharp relief, and, unlike in other genocides, they have been extensively recorded from both the perpetrators' and victims' standpoints. Further, the Holocaust has been a moral watershed that has not only tortured survivors but challenged our civilization. For all these reasons, the Holocaust is worth studying in its own right, in addition to being used as a source that can inform other traumatic situations.

The word experiences ambiguously subsumes events as well as subjective responses to them. This article concentrates on descriptions of stress and trauma inducing events (technically, stressors or traumatic stressors) of the Holocaust. (For the experiential consequences of the events, see **Holocaust, Stress Effects of**.) In what follows, first the cultural backdrop and the traumatic situations of the Holocaust are overviewed. Next, attacks on the morality and spirituality of the victims, including ultimate perversities and evil, are examined. Last, mitigating experiences are examined.

Cultural Background to Holocaust Experiences

The rise of Nazism ruptured an uneasy anti-Semitic equilibrium that had been present to varying degrees over the centuries in Europe, including Germany. The Nazis drew both on this anti-Semitism and on primitive tribal, religious, and ideological myths to demonize, dehumanize, and scapegoat Jews. Thus, Jews were portrayed variably as predatory monsters, subhuman parasites sucking German blood, and superhuman world conspirators.

To the Jews, many of whom had fought for their various countries, including Germany, and who were frequently at the forefront of local culture, the authorities' portrayals of them were an incredible betrayal. Persecution based on the false propaganda shattered their assumptions about a moral and just world. The total attacks on the deeper humanity and spiritual fiber of the victims made the physical attacks on their survival much harder to bear. The following two sections deal with the events that threatened physical and spiritual survival.

Overview of Stress and Trauma Experiences in Different Traumatic Situations

Wartime Situations

Some traumatic events, such as bombing and evacuation ahead of invading armies, were shared with the general population. Such events were felt to be far less noxious than the additional intentional sufferings for which Jews were earmarked.

The precursors to genocide were the following. In Germany and occupied territories, Jews had to display yellow stars on their clothes. Their identification cards indicated their Jewishness. Laws forbade their entry into public areas, segregated them in ghettos, and appropriated their means of livelihood and property. Jewish children were not allowed to attend schools.

In Germany, Krystallnacht in November 1938 broke the taboo on violence and killing. At government instigation, Jewish synagogues and property were smashed and burned, and Jews were killed. According to the new model of justice, Jews were blamed and collectively fined for the events.

As genocidal plans were ever more intensely implemented, segregation, robbery, and killing were accelerated. In occupied countries, within hours of entering villages and towns, Jews were rounded up and killed by firing squads, burned in synagogues, or beaten to death. Alternately, they were slowly killed by starvation and disease in ghettos.

Extermination camps with gas chambers and crematoria were established to increase the efficiency of killing great numbers of people. Entering such places was like entering hell. The only respite from being killed was temporary slavery, with harsh conditions and cruelty.

Some Jews escaped the Nazis to other countries in the early years. Others hid in forests, cellars, and holes. Some pretended to be non-Jews, which was called open hiding. The tension of hiding could be worse than being caught. Many were either caught or denounced and handed over.

Totality of attacks It should be emphasized that these attacks on Jews were total, relentless, and without mercy. Because the criterion for punishment was having 25% or more Jewish genes, there was no way out, such as conversion. Neither the elderly nor children were spared anything. Indeed, children were a prime target as the carriers of future genes. One and a half million children (90%) in Nazi-occupied Europe were murdered.

For the Nazis, physical and genetic extinction were not enough. Schools, culture (e.g., anything written

by Jews), and even cemeteries were destroyed. No evidence or memory of Jews was to survive.

Postwar

For those who survived the Holocaust, many postwar experiences were extremely stressful. Survivors had to come to terms with having lost most or all their relatives, friends, communities, property, and way of life. Dreams of reunion, taking up life where it had been disrupted, hopes that had sustained victims during their worst times, were now shattered. Worse, some local populations rejected returning Jews, withheld returning their property, expressed anti-Semitic views, and in some cases even killed the survivors.

In such circumstances, survivors had to hide their wounds and cope with the new survival challenges of oppression, political persecution, uprootings, and emigrations. The children who had survived had to cope with all these adult stressor events, as well as with their changed and stressed parents.

Stress and Trauma Experiences on the Moral and Spiritual Levels

In order to put the huge Nazi-inspired killing machine into action, it was essential to deprive Jews of human status. If they were deemed to not be human, then the principles of justice and law would not apply to them any more than they did to cattle or vermin and they could be killed without guilt like such animals. The Nazi machine therefore consciously used every means to first kill their victims' humanity in preparation for their physical killing.

Unrestricted and unabashed propaganda was used to portray the monstrous, parasitic, and demonic conspiracy nature of Jews. Their religion, culture, and values were attacked through constant lies. Personal humiliation and stripping of dignity were important conscious precedents and justifications to personal robbery, damage, and killing. Examples of public humiliations included cutting off old men's beards, public mocking, beating, and being made to perform menial tasks. Laws equated Jews with dogs. "No Jews or dogs allowed" signs appeared in public places. Jews were transported in cattle cars like cattle to their places of slaughter. Degradation during transportation was effected through lack of food and drink, forced lack of privacy, and having to excrete in crowded conditions. On arrival in the concentration camps, the dehumanization continued. Prisoners were herded by dogs and whips, were cursed and beaten, and were branded with numbers. Those not slaughtered immediately had all control taken away. They

had to work like animals, had to obey trivial orders and routine on the pain of death, and had their most intimate human functions such as of ingestion and excretion governed by guards. Even their deaths were undignified. Prisoners were stripped naked, beaten, and herded into communal impersonal killing machines. In other words, in addition to the constant threats to their lives, Jews had to contend with forces that were meant to strip them of their humanity, identity, and everything they cherished and loved, their very spiritual and existential meanings. Their souls were attacked as much as their bodies.

Some attacks were particularly cruel and perverse. They included the forced separation of families. When attempts were made to keep family members together, such as when mothers chose to stay with their babies, this love was punished by killing both the mothers and children. Victims were forced to make perverse choices, sacrificing some in order for all not to be killed. For instance, communities were forced to give up their old and young so that all would not be killed. Compounding this perversity, prisoners were forced to take part in the killing and the body-looting process. Worse, victims had to suppress their emotions in order to survive.

Thus, in addition to being the targets of physical sadism and abuse of unlimited power, victims were forced to shed civilized values, relinquish what they held dear, and even turn against what had made their lives meaningful. Mengele, who like the Angel of Death chose with a motion of his finger who was to live and who to die, became a symbol of the victims' powerlessness. The meaninglessness of the slaughter was highlighted by the banality of the industrialization and bureaucratization of the killing process, which used and parodied all the achievements of modern civilization, including the use of psychological knowledge to inure the killers to continuous killing.

Mitigating Factors and the Truth

In the midst of genocide, there was no lack of devotion and courage among Holocaust victims, who risked and helped one another whenever possible. Sometimes kindness and bravery were shown by outsiders at the risk of their lives. The truth of Holocaust experiences can often be absorbed against the background of survival, courage, and victory of goodness, as in Steven Spielberg's film *Schindler's List*. But the truth is that redemptive experiences were far outweighed by the suffering and pain, ineffectiveness of bystanders, meaningless deaths of millions,

and long-term moral and existential wounds of the survivors.

Stress Effects in Recent Times

Lessons and Challenges Regarding Stress Effects from the Holocaust

Glossary

<i>Holocaust</i>	The genocidal extermination of Jews during World War II.
<i>Stress effects</i>	Biological, psychological, and social responses to stressors; they can form the constituents of traumas and illnesses.
<i>Stressors</i>	Noxious events that actually or potentially threaten life and its fulfillment.
<i>Survivor</i>	A person who has lived through traumas, in this case, the Holocaust.
<i>Trauma</i>	A state of irretrievable loss of a life-promoting equilibrium.
<i>Traumatic stressors</i>	Stressors that lead to trauma.
<i>Traumatic situations</i>	Situations that often lead to trauma.

Just as the experiences of Holocaust survivors (see **Holocaust Survivors, Experiences of**) can serve as a benchmark for the stressor nature of Holocaust traumatic situations, so the range and depth of the consequent stress effects of Holocaust experiences can serve as a standard against which stress effects from other traumatic situations can be compared. Further, because Holocaust stress effects have been well documented for

over 60 years, the progression of stress effects – biological, psychological, and social – can be examined over an individual's life cycle, as well as down the generations.

Stress Effects during the Holocaust

Adults

Although, understandably, not scientifically researched in an extensive manner, reports indicate a wide variety of biological, psychological, and social stress responses associated with roundups and deportation, segregation into ghettos, concentration camps, and being in hiding.

Roundups and deportation During roundups and deportations, severe anxiety and reactive depressions were ubiquitous and were perceived as understandable rather than pathological. However, panic attacks, severe depressions, suicide attempts and completed suicides, and the new development of angina and hypertension in these situations, although still understandable, were indistinguishable from physical and psychiatric illnesses.

The sense in many of the neurotic and psychotic symptoms that also occurred can easily be discerned. For instance, agoraphobia developed in response to the danger of going outside. Hysterical symptoms to avoid deportation and paranoid delusions, such as of the gas man, are also quite understandable. The abeyance of prior neuroses and the development of new ones seemed to be dictated by survival needs.

Ghettos and hiding Anecdotal evidence indicates that stress effects in ghettos overlapped those of the roundups, deportations, and concentration camps. Hiding in some ways was more stressful than being caught because people had to cope with constant isolation in hostile circumstances and the fear of being caught could be worse than actually being caught.

Concentration camps On entering the camps, psychic shock (see **Disaster Syndrome**) was often described subjectively as apathy, exhaustion, and emotional blunting. When apathy and total exhaustion continued, they contributed to the 20–50% who just died without obvious disease soon after entering concentration camps. Older and middle-class people were more prone to such shock. Many of them also committed suicide.

In the psychiatric ward in the concentration camp Teresienstadt, all psychiatric diagnostic categories were reported to occur well above expected rates. The diagnoses included schizophrenia and manic-depression. Reports from other concentration camps also described not infrequent cases of depressions, phobias, paranoias (such as of being poisoned), hallucinations, and psychotic reactions. Most psychiatrically ill prisoners died or were shot if their behavior did not conform to strict rules. Some psychoneuroses and psychosomatic illnesses disappeared, and new ones appeared. In some cases, psychosomatic illnesses that went into abeyance during internment reappeared after liberation.

Most prisoners in concentration camps who were not actively murdered, succumbed to the just-as-lethal extermination process, which included starvation, cold, physical assaults, and disease. Physical symptoms such as stomach cramps, diarrhea, dizziness, and headaches due to a variety of diseases were frequent, although some may have been psychophysiological.

Coping and defenses Most people did what they could to help others and themselves. Mostly nothing could be done except to obey orders, resign oneself to circumstances, and maintain hope deep inside.

The most potent factor in survival was luck. But, in addition, to survive victims had to have a strong desire to live no matter what. Other factors that helped them to survive were the suppression of feelings, dissociation and detachment, and living in small stretches of time. Some were helped by intellectual curiosity, others by magical beliefs, humor, and art. Socially, younger people, those who paired to help one another, and those who had strong beliefs had better chances of survival. Religious beliefs helped some but hindered survival for others. However, hope was essential for everyone. The sudden loss of hope was deadening and could lead to a fast demise through infections such as typhus.

Children

Stressors were larger for children, and their responses to stress were frequently insufficient, especially among the youngest children. Children were often the first to succumb to starvation, cold, and disease,

and they had the highest mortality rates – 90% of Jewish children died in Nazi-occupied Europe. The surviving children's responses were shaped by their developmental phases.

Younger children The younger children's worlds fragmented easily. Stress effects frequently included somatic symptoms such as stomachaches, diarrhea and asthma and uncontained emotions and behavior. Younger children tended also to have relatively more vivid, concrete, and phantastic interpretations of events. For instance, human persecutors were admixed with images of monsters, and separations from parents were interpreted as punishment for being bad.

Older children The older children, especially those beyond the age of seven, experienced dread, fear, grief, despair, anger, and guilt akin to the adults. Their capacities and ingenuity sometimes saved adults.

Few children survived the concentration camps; however, in a relatively privileged part of Bergen-Belsen, children were noted to suffer night anxieties, enuresis, and phobias; to be irritable and aggressive; and to form gangs akin to civilian wayward youth.

Coping and defenses Especially when children felt themselves to be under their parents' protective shields, they could interpret the frightening events in part according to their normal developmental phases. For instance, they could see deportation as an adventure.

From about the age of four on, children's psychological defenses resembled increasingly those of adults in their abilities to dissociate and freeze their emotions and the meanings of events. In addition they had amazing capacities for obedience and discerning that life was at stake. For instance, they separated silently from their parents, were docile with strange caretakers, and kept silent when hidden, even when alone and in the dark for long periods. They assumed and lived out a series of false identities and arranged their psyches as desired.

Children also owed their survival to luck, an inner drive to live, suppressing feelings, and maintaining hope. The latter was often through a tenacious clinging to objects and memories representing loving parents. Being appealing, evoking caring impulses, and being plastic when making various adjustments also helped their survival.

Stress Effects Soon after the Holocaust

Adults

At liberation The joy of liberation was mitigated by continued physical debilitation, which in some

cases led to death. Unfortunately, too, many died of eating food that their frail digestive systems could not handle.

Mental debility from camp life could continue after liberation. For instance, in Bergen-Belsen concentration camp, over 40 schizophrenic and several hysterical survivors maintained the psychiatric symptoms that had helped them to survive hunger, death, and torture during their incarceration. Many of the survivors continued to suffer dulled and blunted affect and decreased memory. Others developed reactive despair and paranoid delusions only after liberation.

Postwar Many postwar stressors were worse than the wartime ones. The reality of murdered families, empty communities, and hostile countrymen shattered the dreams that had kept survivors going. Many let go now and took ill. Some died. The rates for suicide and schizophrenic illnesses rose. Some became chronically depressed. Others developed psychosomatic pains, dizziness, and weight-gain problems, all of which often became chronic. Amenorrhea, dysmenorrhea, abortions, and premature babies were not infrequent.

Coping and defenses Most victims resumed their survivor modes. They cut off emotions and memories, labored for today, and hoped for the future. Many married quickly and had children. Many started to achieve financial security, imbued with new hopes in their children and new countries.

Children

Children also enjoyed their freedom, but came to despair when their parents did not materialize or had changed from those in their dreams. Others grieved at having to leave their foster families. Many children were now treated for tuberculosis and other neglected illnesses, and this could mean further separation from their parents. Many exhibited neurotic symptoms and nonsocial behaviors. On the whole, the children coped, like the adults, by suppressing their emotions and memories and by concentrating on establishing their school and social lives.

Stress Effects over the Years

Adults: The Survivor Syndrome

The wide-ranging and marked biological, psychological, and social effects of the Holocaust came to be recognized only slowly and reluctantly. Psychiatry had to invent diagnostic labels to designate the salient image of the shuffling corpse, and the pervasively psychologically scarred survivor with numerous

symptoms. Survivor syndrome became the most commonly accepted label for these symptoms. Its features, described next, subsumed the many biological, psychological, and social symptoms and illnesses, which occurred in many fluctuating combinations and permutations.

Physical sequelae Research on ex-concentration camp prisoners (the same probably applies to other Holocaust survivors) found that they suffered excessive mortality and morbidity from a great variety of illnesses for decades compared to control populations. Illnesses included tuberculosis and other infections, cancer, hypertension, coronary heart disease, stomach ulcers, digestive disorders, hyperthyroidism, and accidents. Premature aging and arteriosclerosis were also noted.

Survivors also suffered excessive autonomic nervous system psychophysiological symptoms. Common sympathetic (fight-or-flight) symptoms were tension, muscle pains, and digestive and cardiovascular symptoms, parasympathetic symptoms included tiredness, dizziness, lassitude, and exhaustion. In addition survivors relived symptoms such as stomach cramps, diarrheas, and headaches along with other wartime memories or (in somatization) as symbolic substitutes for them. Finally, any of these symptoms could be used hypochondriacally to signal anxieties directly or indirectly related to Holocaust fears.

Psychosocial and psychiatric sequelae Psychosocial sequelae include mainly negative emotions, cognitions, defenses, psychiatric illnesses, and spiritual and existential dilemmas. They, in turn, affected relationships and worldviews.

- Emotions. Anxiety, fear, and terror were the most common emotions, followed by depression. The latter was often associated with suppressed grief and was often complicated by survivor guilt (see **Survivor Guilt**).

- Cognitions. Holocaust events could present as hypermnasias or amnasias. In the hypermnasias, the past events were relived vividly in dreams, nightmares, flashbacks, thoughts, and fantasies. The relived events might not be distinguished from the original ones. They could be especially set off by cues reminiscent of the initial Holocaust events; such cues could act as phobias, which survivors might avoid strenuously. The amnasias, on the other hand, were the consequences of avoidance and a variety of defenses such as dissociation, repression, regression, splitting, and projection. The tension between reliving and avoidance (the two main features of posttraumatic stress disorder, PTSD) was

noted to lead to restlessness, decreased concentration, sleeplessness, memory disturbances, moodiness, emotional lability, irritability, and physiological lability.

- **Psychiatric sequelae.** As in the physical arena, Holocaust stresses led to a wide variety of psychiatric symptoms and illnesses. They could be present from early on or could develop after a latent period (even decades later). Most commonly, anxiety and depression intensified into a range of anxiety and depressive disorders, the latter again associated with unresolved mourning. Dissociative defenses were associated with dissociative symptoms such as depersonalization, projection, and displacement, with suspiciousness, persecutory delusions, nighttime hallucinations, schizophreniform psychoses, and schizophrenia. All of these constellations could emerge years later and usually had Holocaust-laden content.

- **Spiritual and existential sequelae.** Survivors were ubiquitously plagued with moral, identity, spiritual, and existential problems, often causing more distress than the physical and psychological problems. Survivor guilt torments included “Why am I alive, when my family/such good people died?” and “Why did I acquiesce to go left, when my mother was sent right to her death?” Other questions included “How could such injustices occur?” “Where was the world/God?” “What does it all mean?” “Who am I now?” and “What purpose can my life have now?” Survivors could become cynical, lacking confidence in the world and themselves, always ready for further wounds.

Coping and defenses Many survivors did well financially due to their single-minded efforts, and their wives helped in their businesses and ran spotless homes. These were scotomized areas of fulfillment because they were intermingled with insecurity.

Survivors achieved meaning by having children to defeat Hitler’s genocide, bear witness, and execute missions of remembrance. Israel was the political answer to vulnerability. Many survivors found purpose by trying to prevent suffering in others. Thus, survivors provided more than their share of moral leadership, philanthropy and cultural accomplishments.

Children

Like their parents, child survivors also suffered excessive mortality and morbidity rates from all types of illnesses, including psychoses and suicides. Child survivors, unlike their parents, often could not remember the events that still plagued them. This was because of their young age at the time and the strong desire of adults that the children not remember. Thus,

they lived their unhappiness as a saturated solution of unacknowledged turmoil, out of which could crystallize clearer symptoms and illnesses. Child survivors coped, like their parents, by concentrating on survival, the future, their own children, and ameliorating suffering in the world.

Only in the 1980s, in their forties and fifties, were child survivors recognized, and they recognized themselves. They explored their identities and memories beyond the molds that had been arranged by others.

Second-Generation Holocaust Survivors

Instead of making sure that their post-Holocaust children’s experiences were linked to a normal external world, Holocaust survivors often linked their children’s experiences to the Holocaust that still dominated them. The children then became unconsciously attuned to their parents’ Holocaust experiences. For instance, a child was spanked for hopping happily in the park because to the parent this was an affront to all the dead; this child grew up to be a sad adult, pervaded by death, without knowing why. Children also absorbed unconscious roles, such as substituting for dead parents and prior children.

Second-generation children often felt overburdened, overprotected, and frustrated with parents who did not recognize them, yet felt unable to be angry with their fragile parents who themselves craved care and understanding. The children developed both symptoms due to identifying with their parents and symptoms resulting from their own attachment problems and unintegrated identities. These children often copied their parents’ means of coping, such as being devoted to their own children and being prominent in humanist and healing occupations.

Stress Effects in Recent Times

Adult Survivors

As Holocaust survivors reach the ends of their lives, it can be seen that the effects of stress and trauma are lifelong. Retirement, the illnesses of old age, diminished brain function, and helplessness can intensify memories, and, for instance, doctors and nurses may be experienced by survivors as Nazis whose injections kill the sick.

On the other hand, survivors enjoy seeing the generations flourish, and this can reconnect them with their pre-Holocaust memories. It is never too late to resolve guilt and integrate frozen meanings. For instance, many survivors have recently given testimonies to the Spielberg Shoah Foundation and have broken their silence with their children.

Child Survivors

Child survivors, having been recognized and having discovered their own identities, have emerged from hiding, which in a sense they had been in since the Holocaust. Although still suffering, some with increased symptoms like their parents, for many it is more important to retrieve their memories clearly, integrate their Holocaust traumas, and make meaning of their lives. To these retrieve memories, many have visited the places of their traumas and have broken the conspiracy of silence. Once they have regained their identity and memories, they trauma pains can be integrated and new meanings can be forged.

Child survivors have formed local, national, and international groups. They have also given testimonies and feel the special privilege and responsibilities associated with being the last witnesses of the Holocaust.

Second and Subsequent Generations

The integration of the Holocaust by second-generation children has been harder because their Holocaust-derived culture has been pervasive and ego-syntonic. Nevertheless, many have come to realize the sources of their problems and have attempted to resolve them with their parents, including going with them to the places of their suffering. Alternately, they have attempted to work out in psychotherapy who they were and why.

Lessons and Challenges Regarding Stress Effects from the Holocaust

If Holocaust stress and trauma effects are seen a kind of benchmark, what principles can be abstracted from them?

1. Biopsychosocial nature of stress effects. Holocaust stress effects indicate that a wide variety of biological, psychological, and social stress effects may occur in many combinations and are subsumed in a great variety of symptoms and illnesses.

2. Diagnostic categories arising from stress effects. This great variety of symptoms and illnesses challenges us to adopt a nonlinear model in which trauma is like the big bang at the center and the symptoms and illnesses freeze out at different points on different ripples emanating from such a center. Survivor syndrome and PTSD may then be conceptualized as generic entities that subsume stress-derived symptoms and illnesses.

3. Multidimensional nature of stress effects. In addition to the rippling of stresses and traumas into

symptoms and illnesses, the Holocaust, especially, indicates that trauma disrupts the human dimension, including morality, meaning, spirituality, identity, and purpose. The Holocaust further alerts us that stress effects take place in individuals, families, communities, and nations; in children and adults; and across generations.

4. Adaptive as well as maladaptive stress effects. During the Holocaust, many responses were adaptive and later could be elaborated into adaptive concerns that benefited large sections of the population. This must be remembered but not idealized – the suffering far outweighed any beneficial results of the traumatic events.

In conclusion, the stress effects of the Holocaust are very varied, deep, and intense. The sense of the overwhelming nature of the effects and the despair about being able to do anything about them parallels our general avoidance of trauma and despair about being able to treat it. Yet the fear is excessive, and helpful recognition of even the greatest traumas can be very beneficial and rewarding to both survivors and to those in contact with them.

Characteristics of Homeostatic Systems

Problems with the Concept of Homeostasis and
Alternative Terminology

Glossary

Homeostasis The ability of an organism to maintain the internal environment of the body within limits that allow it to survive; self-regulating processes that return critical systems of the body to a set point, or range of operation, consistent with survival of the organism.

Characteristics of Homeostatic Systems

Homeostasis is highly developed in warm-blooded animals living on land, which must maintain body temperature, fluid balance, blood pH, and oxygen tension within rather narrow limits while at the same time obtaining nutrition to provide the energy to maintain homeostasis. This is because maintaining homeostasis requires the expenditure of energy. Energy is used for locomotion as the animal seeks and consumes food and water, for maintaining body temperature via the controlled release of calories from the metabolism of food or fat stores, and for sustaining cell membrane function as it resorbs electrolytes in the kidney and intestine and maintains neutral blood pH.

Homeostasis also refers to the body's defensive mechanisms. These include protective reflexes against inhaling matter into the lungs, the vomiting reflex as a protection to expel toxic materials from the esophagus or stomach, the eye blink reflex, and the withdrawal response to hot or otherwise painful skin sensations. Also included is the defense against pathogens through innate and acquired immunity.

According to Cannon, "Bodily homeostasis . . . results in liberating those functions of the nervous systems that adapt the organism to new situations, from the necessity of paying routine attention to the management of the details of bare existence. Without homeostatic devices we should be in constant danger of disaster, unless we were always on the alert to correct

voluntarily what normally is corrected automatically. With homeostatic devices, however, that keep essential body processes steady, we as individuals are free from such slavery – free to enter into agreeable relations with our fellows, free to enjoy beautiful things, to explore and understand the wonders of the world about us, to develop new ideas and interests, and to work and play, untrammelled by the anxieties concerning our bodily affairs."

The body has a considerable redundancy or margin of safety when it comes to many of these mechanisms. There are two kidneys and adrenal glands in case one fails, and the digestive tract is able to function adequately for food absorption even if intestinal length is shortened. Moreover, individuals are able to survive with one lung. And the cardiovascular system has a number of devices to maintain blood pressure after considerable blood loss. Finally, as Cannon notes, the body displays considerable resilience in the face of injury and after surgery to compensate for lost function.

Problems with the Concept of Homeostasis and Alternative Terminology

Yet there are paradoxes and problems with the notion of a set point that is always maintained. In discussing obesity, Cannon states, "What leads to the storage of fat in large amounts – sometimes in grotesquely large amounts – in some persons, and in slight amounts in others, is not well-understood." This and other aspects of pathophysiology, particularly in response to stress, has forced a reevaluation of the processes that reestablish homeostasis in the face of a challenge and that, under some circumstances, exacerbate disease (see **Allostasis and Allostatic Load**).

Another problem with homeostasis is that, taken literally, it is a rather static concept, akin to the notion of equilibrium in classical thermodynamics; in real life, an organism experiences changing set points around which it maintains stability over a finite period of time. Moreover, unlike the closed systems of classical thermodynamics, a living organism is an open system in which energy and matter flow in and out, with equilibrium being replaced by a steady state. Cannon recognized this and used the term steady state; he even suggested that homeodynamics might be a better term than homeostasis.

The same problem was also recognized by a number of other authors. Nicolaidis introduced the term homeorheusis in 1977; here stasis is replaced by rheusis, meaning "something flowing." Mrozovsky introduced the term rheostasis in 1990, "a condition

or state in which, at any one instant, homeostatic defenses are still present but over a span of time there is a change in the regulated level, or set point of a system.” He considered this concept advantageous in explaining how organisms adjust to changing environments such as the seasons of the year by storing body fat or changing reproductive physiology, and he believed that rheostasis allows for the kinds of physiological plasticity that is involved in evolution.

Heterosexism
Gender Beliefs and Gender Stress
Homophobia
Moral Condemnations of Homosexuality
Antigay Violence
The Stress of Being in the Closet

Glossary

<i>Being in the closet</i>	Psychological and behavioral activities intended to keep one's homosexuality a secret.
<i>Coming out</i>	Admitting one's homosexuality to oneself or revealing it to others.
<i>Dissociation</i>	A psychological mechanism that allows individuals to keep unwanted or anxiety-producing information out of their awareness.
<i>External homophobia</i>	The irrational fear and hatred that heterosexuals feel toward gay people.
<i>Gay bashing</i>	Physical violence directed at people because they are gay.
<i>Gender beliefs</i>	Cultural ideas about what constitutes the essential qualities of men and women.
<i>Gender identity</i>	An individual's psychological sense of being either a man or a woman.
<i>Heterosexism</i>	A belief system that naturalizes and idealizes heterosexuality and either dismisses or ignores a gay subjectivity.

Internal/ internalized homophobia
Moral condemnations of homosexuality
Outing

The self-loathing gay people feel for themselves.

Beliefs that regard homosexual acts as intrinsically harmful to the individual, to the individual's spirit, and to the social fabric.

The unwanted revelation of an individual's homosexuality to others by a third party.

Sexual orientation

A person's attraction to members of either the same sex (homosexual), the other sex (heterosexual), or to both sexes (bisexual).

Sodomy laws

Legislation that criminalizes homosexual behavior, ruled unconstitutional by the United States in 2003 by the Supreme Court.

Throughout the life cycle, gay, lesbian, and bisexual (GLB) individuals experience significant stressors that are a consequence of society's antihomosexual attitudes. Some of those attitudes and the stresses they engender are discussed here.

Heterosexism

Those with GLB identities are routinely stressed by cultural expectations that each individual have a heterosexual identity. This is known as heterosexism, a belief system that naturalizes and idealizes heterosexuality and either dismisses or ignores a gay subjectivity.

Heterosexism does not necessarily imply malice or ill will toward GLB individuals; idealizing oneself

does not necessarily require denigrating those who are different. However, heterosexist ideology typically frames its antihomosexual arguments in terms of the normal, the natural, or the traditional. Such arguments, sometimes implicitly and at other times explicitly, tend to equate identities that are not conventionally heterosexual with immorality and can rationalize condemnations of same-sex feelings and behaviors. Heterosexist attitudes are pervasive in many cultures, and they inevitably place gay people in the awkward and often stressful position of either (1) keeping their homosexuality a secret (being in the closet) or (2) having to reveal they are gay (coming out) to disprove cultural myths and assumptions about homosexuality. The most dramatic example of this stressful dilemma can be seen in the U.S. military's Don't Ask, Don't Tell policy, under which either revealing oneself to be gay or being found out to be gay can lead to a discharge.

In Western culture, most books, plays, movies, and print and television ads contain naturalized depictions of heterosexuality. "Boy meets girl, boy loses girl, boy gets girl" are the common elements of a heterosexist script. Heterosexism renders gay lives so invisible that at the time of writing this chapter, there is enormous media attention and controversy over *Brokeback Mountain*, a film in which the two male leads fall in love. Many heterosexual people have openly stated either their reluctance or opposition to seeing two men kiss on the silver screen.

Common expressions of heterosexism include valuing heterosexual relationships above homosexual ones, unquestioned opposition to gay parenting regardless of a gay parent's actual qualities as a parent, and the belief that lesbians and gay men are unsuited to teach small children, to serve in government, or to practice medicine. Heterosexist assumptions lead to separating men and women from one another in locker rooms. Yet gay teenagers may be stressed by having to hide any possible arousal they may experience on seeing naked peers in the locker room's ostensibly asexual environment. Similarly, a heterosexist world may make it difficult for elderly gay couples to openly live together in either retirement communities or assisted living programs.

A decade ago, marriage was implicitly assumed to be a ritual reserved for heterosexual couples. As a result of lawsuits initiated by gay couples in the 1990s and following the 2003 decision to allow same-sex marriage in Massachusetts, many other states rewrote their constitutions to specifically state that marriage should only be between a man and a woman. The stated impetus for these constitutional changes is often termed the "defense of marriage." Yet laws ostensibly written to preserve heterosexual relations

inevitably create stress for gay couples and their families. The U.S. General Accounting Office has computed over 1000 rights, privileges, and benefits accrued through marriage. Consequently, the heterosexist denial of legal marriage to long-term, committed gay couples adds to the latter's stress by denying them and their families basic needs, including clearly defined inheritance rights, pension benefits, survivor death benefits, custody rights in cases of divorce, and health benefits, just to name a few. A growing literature also indicates increased psychological resilience in those who marry; denying legal marriage to same-sex couples denies them marriage's psychological benefits as well.

Gender Beliefs and Gender Stress

Any discussion of antihomosexual stressors necessitates some discussion of both scientific and popular heterosexist beliefs about gender and sexuality. Modern sexology distinguishes a person's gender identity, or the sense that one is a man or a woman, from the person's sexual orientation, whether one is attracted to members of the same sex (homosexual), the other sex (heterosexual), or to both sexes (bisexual). However, the general culture uses conventional heterosexuality as an organizing frame of reference and frequently conflates the categories of gender identity and sexual orientation. These common but mistaken gender beliefs include the notion that an attraction to men is a female trait or that gay men feel and act like girls. Although such mundane gender beliefs can be stressful because they misrepresent GLB people, GLB individuals are not alone in having to contend with them. Gender beliefs also include ideas about the kind of shoes men should wear (construction boots rather than spike heels) and the kind of career a woman should choose (becoming a nurse rather than a doctor). In other words, gender beliefs are not confined to the realm of sexuality; they concern themselves with many aspects of day-to-day life.

Gender beliefs play an important role in the development of gender identity. One may be born with an anatomical gender, but one's psychological gender is a later acquisition that has both cognitive and affective elements. How one's gender identity actually develops is not precisely known, although empirical data suggest it is a long and complex process. Clinical work shows that a person's sense of being a man or a woman can involve processes that are entirely dependent on attitudes from the external environment over extended periods of time. Children must learn a psychological construct of gender that is based not solely on anatomy but also on myriad cultural and familial clues (e.g., boys like to play ball or girls are

made of sugar and spice). Consequently, the meanings of, for example, aggression in girls or a lack of athletic interests in boys can be internalized along a family or cultural model that codes these attributes as gender-specific. From this developmental perspective, a gender identity can be thought of as the accretion of experiences or interactions with the external and internalized gender-coding environment. That is to say, a person's gender is an activity occurring in a relational matrix.

For children who grow up to be heterosexuals, conformity to conventional gender beliefs and norms can sometimes offer a sense of comfort. However, gender beliefs can be stressful to heterosexuals as well. Real men and real women are powerful cultural ideals against which all men and women may unfavorably compare themselves. However, GLB individuals must contend with the dissonance created by early same-sex attractions and their learned cultural beliefs about the relationship between homosexuality and gender. Consequently, in some children who grow up to be gay, their developing gender beliefs about the meanings of their homoerotic feelings may lead them to question their own gender identities.

Seen from this perspective, children who grow up to be gay may be gender stressed. This is a process that can occur over a protracted period of time as early homoerotic feelings become linked to other gender-nonconforming interests and as these children come to realize that they are failing to meet the cultural and social expectations of their assigned gender. This is commonly seen in gay men who were effeminate boys, often denigrated for being sissies. However, even gay men who were more conventionally masculine as children recall gender stresses in their attempts to integrate their same-sex feelings into a male identity. Sometimes gender stress can lead to gender confusion. Clinically, gender confusion can be expressed as "If I am attracted to boys, I must be like a girl." But it might also include responses such as "I am depraved," "I will be alone," or "I have sinned." These are common and stressful gender beliefs associated with transgressing gender boundaries.

Homophobia

George Weinberg is generally credited with coining the term homophobia. He defines external homophobia as the irrational fear and hatred that heterosexuals feel toward gay people and internal (or internalized) homophobia as the self-loathing gay people feel for themselves. Weinberg suggests several origins of homophobia: the religious motive, the secret fear of being homosexual, repressed envy, and the threat to values. In fact, plethysmographic studies

demonstrate that in some men, homophobic attitudes may defend against unwanted homoerotic feelings.

Weinberg's early work has been followed by an ever-expanding literature devoted to studying intolerance of homosexuality. Other factors thought to contribute to homophobic attitudes include (1) rare contact with GLB people, (2) a lack of homosexual experiences of one's own, (3) perceiving that one's own community does not accept homosexuality, (4) living in communities where homosexuality is unacceptable, (5) being older, (6) being less educated, (7) identifying oneself as religious or as belonging to a conservative religion, (8) being less permissive about sexuality in general, and (9) expressing high levels of authoritarianism.

In 1954, the U.S. Supreme Court ruled in *Brown v. The Board of Education* that racial segregation was unconstitutional. In support of that decision, the justices cited the psychological literature of the time that demonstrated how stressful and harmful racism was to the self-esteem of black children. Just as one cannot grow up black in America without internalizing racism, one cannot grow up gay without internalizing homophobic and other antihomosexual attitudes. Self-hatred is extremely stressful. In the clinical setting, internalized homophobia can present as low self-esteem, difficulty in sustaining relationships, estrangement from one's family of origin, work difficulties, or self-medication with drugs or alcohol to reduce stress-induced anxieties.

Homophobia is often expressed in the association of male homosexuality with effeminacy. Sissies of all ages are regularly targets of homophobia. The low social status accorded to sissies leads some parents, fearful that their children will grow up to be gay, to seek professional treatment to change the behaviors of their effeminate sons. However, when mental health professionals and parents join the social chorus of derision, presumably for a child's own good, being labeled effeminate at an early age can entail great stress and suffering.

Although some gay men are effeminate, assuming that all gay men are effeminate falls under the rubric of stereotyping. In addition to disdain for effeminacy, homophobia can be expressed in other stereotypes, clichés, or caricatures of sexual identities. Common stereotypes of gay men describe them as being sexually promiscuous or compulsive, having a talent for the arts, being mama's boys, or lacking in courage. Common stereotypes of gay women label them as being man-haters, tomboys, overly aggressive, or physically unattractive. Both gay men and women have been stereotyped as sexual predators or being fated to lead single lives of loneliness. Clinical experience has demonstrated that it is extremely stressful

for GLB individuals to have to constantly prove to heterosexual families, friends, employers, and co-religionists – and sometimes to themselves – that these are just stereotypes.

Moral Condemnations of Homosexuality

People who morally condemn homosexuality regard homosexual acts as intrinsically harmful to the individual, to the individual's spirit, and to the social fabric. Those who morally condemn same-sex activities believe that the tradition of philosophical, legal, and religious opposition to homosexuality is, in and of itself, sufficient reason to forbid the open expression of homosexuality in the modern world. Although critics of these condemnations attribute them to homophobia, antihomosexuality stemming from moral beliefs is often more complex. For example, religious and secular social conservatives who morally condemn homosexuality claim they do so out of love or concern for something else. In today's culture wars, such individuals and groups actively and vocally oppose gay and lesbian civil rights at the municipal, state, and federal level. Their political activities, which arise from their moral condemnations, are an ongoing source of stress for the GLB community.

The most severe forms of moral condemnation are embodied in laws that criminalize homosexual behavior, once referred to as sodomy laws. In the mid-twentieth century, homosexuality was illegal in all 50 states. By 2003, only 13 states still had such laws. Although rarely enforced, they were often a source of stress for GLB populations. Selective enforcement of sodomy laws allowed antihomosexual law enforcement communities to harass and discriminate against gay citizens. Furthermore, it was routinely argued in states with sodomy laws that gay couples, as potential criminals, should not be allowed to adopt their foster children. Obviously, criminalizing the sexual behaviors felt to be part of one's normal sexuality is extremely stressful to those so charged. In 2003, however, the U.S. Supreme Court ruled in the case of *Lawrence and Garner v. Texas* that all state sodomy laws were unconstitutional.

Moral condemnations of homosexuality hampered the early public health response to the AIDS epidemic and, in the process, added significantly to the losses and stress of the GLB community. Initially – and incorrectly – perceiving AIDS to be primarily a disease of gay men, public health systems were unprepared to talk frankly about either homosexuality or the kind of sexual practices that transmitted the virus. In 1987, 6 years after the initial cases were identified, President Reagan first mentioned the word "AIDS." Although teaching safe sex practices to sexually

active individuals was important in slowing the spread of the epidemic, moral disapproval of homosexuality made federal funding of such educational efforts illegal. Even though most global AIDS cases have been transmitted heterosexually, many still argue, usually in a condemnatory way, that homosexuality causes AIDS rather than unsafe sexual practices that spread the virus. After experiencing thousands of preventable deaths, it is not unsurprising that many in today's GLB community feel their own government does not value their lives.

In their more subtle forms, moral condemnations of homosexuality include an attitude known as love the sinner, hate the sin. In earlier historical eras, religious authorities condemned sodomites to eternal damnation, to prison, and sometimes even physical torture. However, science and medicine's redefinition of homosexuality, as well as the growing number of openly gay and lesbian voices, had an enormous impact on religious attitudes. Consequently, religious groups were forced to integrate the accumulating scientific data regarding the presumptive etiologies and naturalness of homosexuality.

Today's religious authorities find themselves having to contend with the spiritual needs of a growing number of gay people, as well as those of their families. Some religious denominations (i.e., Episcopalians and the United Church of Christ) have adopted an accepting model of homosexuality and openly embrace lesbian and gay worshippers. Some denominations even admit openly gay men and women as priests, rabbis, and ministers. However, acceptance has not been the majority approach.

Many religious authorities have instead chosen to embrace the homosexual but not the homosexuality. Contrary to mainstream scientific findings, antihomosexual religious authorities believe one chooses to be a homosexual despite the prohibitions against it – "choice" being a charged word in moral debates about homosexuality. In recent years, antihomosexual groups have been publicizing so-called sexual conversion or reparative therapies intended to change homosexuals. Rather than excluding gay people, they invite them back into the religious fold if they change their ways. However, the overstated claims surrounding conversion therapies have generated much interpersonal stress in many religious GLB individuals, particularly when family members pressure them to undergo the process. The public relations effort promoting these treatments is worrisome because (1) their efficacy is questionable, (2) the etiological theories on which they are based are not supported by current scientific research, (3) the practitioners of these treatments incorrectly label homosexuality as a mental disorder, (4) there is sparse documentation

of the cure rates and when the rates are documented they are quite low (27–35%), (5) long-term results are rarely validated, (6) there are an increasing number of anecdotal reports that these treatments may cause harm, and (7) the false hopes raised in offering such treatments often delay individuals or their family members from accepting them as gay. In fact, the American Psychiatric Association has issued a position statement asking ethical practitioners to refrain from such practices and to do no harm.

Religious beliefs that disapprove of homosexuality constitute substantive, ongoing stressors in the lives of gay people, particularly for those who had strict, fundamentalist, or orthodox religious upbringings. Because they may no longer be participating in religious activities, they are often estranged from their communities where family, social, and religious activities are deeply intertwined. The social isolation that ensues from gay people's fear of moral condemnation can also be stressful.

Antigay Violence

In 1990 the federal government passed a law ordering a study of hate crimes, including attacks on gay men and women, the first time a federal civil rights law covered sexual orientation. In one common presentation of gay-bashing, gangs of young men descend on neighborhoods where gay people meet. Armed with bats, clubs, or other weapons, they attack anyone they believe to be gay.

Since the much-publicized beating to death of Matthew Shepard in 1998, there has been increased awareness and documentation of antigay violence and gay-bashing incidents. Publicized cases have also led to the open articulation of previously unspoken cultural beliefs, for example, the belief that violence is an excusable response to an unwanted sexual advance from a gay man. Termed the "gay panic defense," no court has yet accepted it as justification for antigay violence. Its underlying rationale is that gay victims are responsible for provoking the violence against them. Others, however, argue that antigay violence is the inevitable outgrowth of unexamined and unstated beliefs implicit in homophobia, heterosexism, and moral condemnation. They argue that not everyone can distinguish the sinner from the sin and that those who marginalize homosexuality are either directly or indirectly responsible for the brutality against gay men and women.

Leaving the unanswered question of antigay violence's origins aside, most GLB people have legitimate concerns about it. Holding one's partners hand in public or a chaste kiss may provoke a physical attack.

Furthermore, antigay violence is believed to be an underreported phenomenon because its victims are often reluctant to come forward. Victims often blame themselves for being in the wrong place at the wrong time. Even gay people who have never been assaulted are sensitive to the ways in which members of the dominant culture, both in positions of authority or on its margins, can make threats and do as they please.

The Stress of Being in the Closet

In their developmental histories, gay men and lesbians often report periods of difficulty in acknowledging their homosexuality, both to themselves and to others. Children who grow up to be gay rarely receive family support in dealing with antihomosexual prejudices. On the contrary, beginning in childhood – and distinguishing them from racial and ethnic minorities – gay people are often subjected to the antihomosexual attitudes of their own families and communities. Consequently, gay men and lesbians may spend long periods of their lives unable to acknowledge their homosexuality, either to themselves or to others. Throughout childhood and the life cycle, even the suspicion of being gay can lead to teasing, ridicule, family censure, or even violence. Consequently, many gay people come to regard their homosexuality as an unpleasant fact they would rather not know about themselves, let alone admit to others; their homosexuality must be kept out of their awareness and separated from their public persona. The psychological means by which they accomplish this separation is called dissociation.

Dissociation, of course, is not limited to gay men and lesbians. Almost everyone is capable of pushing unwanted knowledge out of one's awareness. However, given some of the consequences of being openly gay – estrangement from family, loss of employment, loss of home, loss of child custody, loss of opportunity, loss of status and even blackmail – dissociation may seem a viable option for survival. Some closeted gay people can reflexively speak without revealing the gender of the person being discussed or without providing any gendered details of his or her personal life. Some closeted gay people marry and, on the surface, live their lives as if they were typical heterosexuals. Although some closeted gay men and women may not act on their homosexual feelings, others may develop secret sexual lives. In fact, through dissociation, a whole double life can be lived and yet never be acknowledged.

This psychological effort to solve one problem, however, creates others. It is stressful to continuously hide significant aspects of the self or to vigilantly

separate aspects of the self from others. Constantly hiding creates difficulties in accurately assessing other people's perceptions of oneself as well as recognizing one's own strengths. Dissociation's impact on self-esteem can also make it difficult to feel one's actual accomplishments as reflections of one's own abilities. Hiding takes its toll, particularly because the psychological effort needed to maintain a double life often leads to errors in judgment that further add to one's stress. Maintaining a heterosexual identity while engaging in secret homosexual activity may inevitably lead a closeted individual into compromising situations.

Those who find this psychological split untenable may come out as either gay, lesbian, or bisexual. Coming out involves putting into words the feelings and ideas that previously had no acceptable form of open expression. Calling oneself gay or lesbian is an effort to reach some measure of self-acceptance. The process is not just about revealing oneself to others. It is a realization that previously unacceptable homosexual feelings or desires are actually part of one's self. Coming out is fraught with danger because of the social stigma attached to homosexuality due to antihomosexual attitudes in the culture. Given the difficulties associated with revealing a gay identity, it may seem a wonder that anyone comes out at all.

For some, coming out may be against their will, precipitated by an act of malice. In such cases of outing, a hidden homosexual identity is exposed by those seeking revenge, political advantage or financial gain. Fear of being outed is a major stressor in the lives of many closeted GLB individuals. However, those who come out of their own accord describe the experience positively, as "a switch being turned on," "coming home," or "discovering who I really am." For them, as stressful as it may be to come out, it may be even more stressful to stay in the closet.

Glossary

<i>Anger</i>	An unpleasant emotion, ranging in intensity from irritation or annoyance to fury or rage, that is an emotional expression of hostility.
<i>Cynicism</i>	A component of hostility characterized by the belief that others are motivated by selfish concerns.
<i>Hostile interactional style</i>	A style of interaction characterized by the tendency to challenge, evade questions, and become easily irritated.
<i>Hostility</i>	A general cognitive personality trait including a devaluation of others' worth and motives, an expectation of wrong-doing in others, an oppositional approach to others, and a desire to see others harmed.
<i>Mistrust</i>	A component of hostility characterized by the belief that others are likely to be provoking and hurtful.
<i>Type A behavior pattern</i>	The early conceptualization of coronary-prone behavior that featured two key components: excessive time urgency and free-floating hostility.

History of the Concept

In the 1960s, the concept of the type A behavior pattern was introduced by cardiologists Meyer Friedman and Ray Rosenman to describe individuals who possessed excessive time urgency and free-floating hostility and who, by virtue of this behavior pattern, were believed to be coronary-prone. This conceptualization fostered hundreds of investigations in the 1970s and 1980s aimed at replicating early associations with coronary disease, refining its measurement, and understanding its physiological underpinnings.

In 1980, a classic paper was published by Williams and his colleagues that suggested that the hostility component of the type A behavior pattern was its toxic core ([Figure 1](#)). Angiography patients were divided by gender, type A behavior, and hostility, and these classifications were related to occlusive disease. For both males and females, hostility was a better predictor of $\geq 75\%$ occlusion than type A behavior. This seminal investigation was subsequently replicated in a large number of studies using a variety of subjects and study designs and resulted in a shift in thinking away from type A behavior toward hostility as a key coronary-prone behavior.

Conceptualization

Hostility is a negative attitude toward others consisting of enmity, denigration, and ill will. It is a stable personality trait with stability coefficients of 0.85 over 1 or 4 years, 0.67 over 5 years, and 0.40 over 24 years. Hostility appears to be a multidimensional trait with from two to four factor analyzed components. There is general agreement that the two key components are cynicism, or the belief that others are motivated by selfish concerns, and mistrust, or the belief that others are likely to be provoking and hurtful. Other components include such things as a hostile attributional style, which is the tendency to construe the actions of others as involving aggressive intent, and a hostile interactional style characterized by the tendency to challenge others, evade questions, and become easily irritated. Smith has argued for a transactional view of hostility, which includes aspects of both the person and the environment. When both hostility and social support are considered jointly, three distinct components emerge: (1) nonhostile and high socially supported healthy individuals, (2) highly hostile and low socially supported submissive individuals, and (3) highly hostile and high socially supported aggressive individuals.

Although hostility is often linked to the risk factors of anger and aggression, it is distinct from them in that it refers to a cognitive personality trait. Anger is an emotion that includes reactions ranging from mild irritation to intense anger and can be a transitory feeling state or an enduring predisposition. Aggression is a behavior defined as attacking or hurtful actions toward others, whether the harm is physical or verbal. Correlations among these characteristics are moderate, suggesting that they are related, but nonetheless distinct.

Figure 1 Relation of type A behavior pattern, hostility, and gender to presence of significant coronary occlusions. From Williams, R. B., et al. (1980). *Psychosomatic Medicine* 42, 539–549, with permission.

Studies that have examined the sociodemographic correlates of hostility have found that it increases with age, is higher in men than in women, is higher in minorities than in Caucasians, and is higher in individuals of lower than in those of higher socioeconomic status. Moreover, there is consistent evidence that hostility is associated with smoking, elevated body mass index, and heavy alcohol consumption. Since these correlates are, in themselves, risk factors for disease, they can serve as confounders for any association between hostility and disease. Confounding in this case would be making the mistake that the true association is between hostility and coronary disease, when in fact the true association is actually between one or more of these established coronary risk factors (which are linked to hostility) and coronary disease. It is important to control for these potential confounders in the design or analysis of studies assessing the health impact of hostility.

Assessment

There are three popular assessment measures of hostility, all of which have subscales. Two of these are self-report questionnaires and the third is a behavioral rating. [Table 1](#) presents selected items from these scales.

The Cook-Medley Hostility Scale

The Cook-Medley Hostility Scale is a subscale of the Minnesota Multiphasic Personality Inventory

Table 1 Selected items from the most popular hostility assessment scales

SELF-REPORT QUESTIONNAIRES

Cook-Medley Hostility Scale: Mark each item as “true” or “false”

Cynicism	I think most people would lie to get ahead
	Most people are honest chiefly through fear of being caught
Mistrust/hostile attributions	It is safer to trust nobody
	I tend to be on guard with people who are somewhat more friendly than I had expected
Hostile affect	Some of my family have habits that bother and annoy me very much
Aggressive responding	I have at times had to be rough with people who were rude or annoying

Buss-Durkee Hostility Inventory: Mark each item as “true” or “false”

Expressed hostility	I lose my temper easily but get over it
	When people yell, I yell back
	I raise my voice when arguing
Experiential hostility	I don't seem to get what's coming to me (resentment)
	I know that people tend to talk about me behind my back (suspicion)
	My motto is "Never trust strangers" (mistrust)

BEHAVIORAL RATINGS

Interpersonal Hostility Assessment Technique: Behavioral ratings from a structured interview, based upon style of interaction

Direct challenges	Direct or explicit challenge of the question or the interviewer
Indirect challenges	Implication that the answer was obvious or the interviewer was stupid for having asked it
Hostile withholding or evasion	Avoidance or refusal to answer a question, associated hostile tone and intent not to answer
Irritation	Irritated tone, impatience, exasperation with the interview or interviewer, aroused reliving of negative events, condescension or snide remarks, harsh generalizations, punched words with angry emphasis

(MMPI) that is composed of 52 true–false items. Several factor analyses of this scale have produced slightly different solutions ranging from two to four factors. The two-factor solution includes the components of cynicism and mistrust/hostile attributions. The four-factor solution includes the components of cynicism, mistrust/hostile attributions, hostile affect, and aggressive responding. Studies of hostility as a risk factor have used the entire scale, the cynicism subscale, or the Abbreviated Cook-Medley (ACM) with the four subscales. The major limitation of the Cook-Medley scale is that it correlates consistently with depression and anxiety, characteristics that may be outside of the conceptual domain of hostility.

The Buss-Durkee Hostility Inventory

The Buss-Durkee Hostility Inventory is composed of 66 true–false items that are grouped into seven subscales: assault, indirect hostility, irritability, negativism, resentment, suspicion, and verbal hostility. In factor analytic studies, it has been consistently shown to assess two correlated dimensions, expressive hostility and experiential hostility. Expressive hostility assesses verbal and physical aggressiveness and is more highly correlated with antagonism than with neuroticism. Experiential hostility assesses the subjective experience of resentment, suspicion, mistrust, and irritation and is more highly correlated with neuroticism than with antagonism.

The Interpersonal Hostility Assessment Technique (IHAT)

The IHAT is an evolution of the structured interview for type A behavior in which the focus is on behavioral ratings of a hostile interpersonal style. It provides more objective criteria for assessing hostility than the subjective judgments that have characterized past interview ratings. Four types of hostile behaviors are rated from type A interview scripts, including direct challenges to the interviewer, indirect challenges to the interviewer, irritation, and hostile withholding of information or evasion. IHAT ratings have been correlated ($r = 0.32$) with potential for hostility ratings from the structured interview for type A behavior and have been shown to be stable over a 4-year period ($r = 0.69$).

Link to Physical Disease in Longitudinal Studies

Figure 2 summarizes the longitudinal studies that have examined a link between hostility and physical disease. Approximately half of all longitudinal studies have found the expected association.

Figure 2 Percentage of prospective studies that have found a positive link between hostility and physical health.

Coronary Heart Disease in Healthy Subjects

To date there have been 12 longitudinal studies that have examined the role of hostility on the incidence of coronary heart disease (coronary mortality or myocardial infarction), six longitudinal studies that have examined the role of hostility on coronary heart disease (CHD) mortality, and two longitudinal studies that have examined the role of hostility on subclinical cardiovascular disease. Positive associations were found in five (41.7%) of the CHD studies, three (50%) of the CHD mortality studies, and two (100%) of the subclinical cardiovascular disease studies. Evidence exists that hostility is equally predictive in men and women, older and younger subjects, African American and Caucasian subjects, and the total scale and the abbreviated subscales.

Since hostility is embedded in a behavioral complex of other risk factors for coronary disease that includes lower education, higher body mass index, current smoking, and heavy alcohol consumption, these risk factors must be controlled for in multivariate analyses to avoid the problem of confounding. When the prospective studies that showed significant associations were examined for the adequacy of their control for these confounders, none of the studies controlled for all of these factors and most controlled only one or two of them. In one study, direct adjustment for these potential confounders eliminated a prior positive association. This suggests that any link between hostility and CHD may not be independent of standard risk factors but instead may be mediated by them.

Total Mortality in Healthy Subjects

There have been nine prospective studies of the link between hostility and total mortality. Of these, five (55.6%) found a positive association. The positive findings included both men and women and included both the total Cook-Medley scale and an abbreviated

version. None of these studies controlled for education, and very few controlled for body mass index. Thus, the bulk of the evidence suggests that an association exists. It is not known, however, whether this association is independent of, or mediated by, established risk factors.

Coronary Heart Disease in High-Risk Subjects

There have been nine prospective studies of hostility and clinical CHD outcomes in patients with evidence of existing coronary disease. Of these, six (66.5%) found a positive association. These studies are characterized by inadequate control for confounding, with one exception. In a study of postmenopausal women with existing CHD from the Heart and Estrogen/Progestin Replacement Study (HERS) cohort, both the total Cook-Medley scale and the cynicism subscale predicted total CHD events after excellent controls for demographic and CHD risk factor confounders in multivariate analyses. Thus, the evidence is slightly stronger that an association, which is independent of the risk incurred by established risk factors, exists between hostility and CHD in high-risk patients than in their healthy counterparts.

Mechanisms of Association

There are three key mechanisms by which hostility may be associated with physical disease. The first is a direct mechanism whereby hostility triggers neuroendocrine pathogenic mechanisms for physical disease. The second is an indirect association whereby hostility fosters elevations in established risk factors and these risk factors increase risk for physical disease. The third suggests that hostility is embedded in a constellation of psychosocial risk factors, which together increase the psychosocial burden and, concomitantly, the risk of physical disease. Literature on potential mechanisms is growing rapidly, particularly evidence for a direct physiological link between hostility and disease.

Physiological

There is consistent evidence that hostility exerts a direct effect on CHD and total mortality through the mechanisms of amplified cardiovascular reactivity and neuroendocrine responses to stressors. Evidence exists for an association between hostility and such pathophysiological mechanisms as heart rate and blood pressure reactivity, increased platelet aggregation, vasoconstriction of atherosclerotic arteries, silent ischemia, decreased ejection fraction, decreased threshold for ventricular fibrillation, and decreased heart rate

variability. There also is evidence that hostility activates the sympathetic branch, and/or suppresses the parasympathetic branch, of the autonomic nervous system, mediated through epinephrine, norepinephrine, testosterone, and serotonin. Recent research suggests other possible physiological mechanisms involving the metabolic syndrome and inflammatory processes. Hostility has been associated with the metabolic syndrome of high levels of plasma lipids, insulin resistance, visceral body fat, and elevated blood pressure. Hostility has also been associated with inflammatory processes, specifically pro-inflammatory cytokines, tumor necrosis factor- α , and interleukin-6.

Health Behaviors

Evidence is accumulating that hostility is associated with smoking, heavy alcohol consumption, a sedentary lifestyle, obesity and overweight, elevated blood pressure, and lowered HDL cholesterol. Moreover, hostile individuals may be more likely to ignore health warnings and fail to comply with medical regimens. Two studies exist that have directly tested this model by examining the association between hostility and CHD before and after adjusting for established risk factors. One found that the association was maintained after adjustment; the other found that the association was eliminated. Thus, there is evidence from one study to support this mechanism.

Psychosocial Vulnerability

Hostile individuals not only may be hostile but also may have other psychosocial characteristics that have been observed to be coronary prone, including depression, anxiety, low social support, and/or general distress. Correlations between measures of hostility and these other psychosocial risk factors are between 0.25 and 0.30. Thus, it may not be the hostility alone but the overall adverse psychosocial risk factor profile that is associated with physical disease. For example, one study found that general distress was a better predictor than hostility of 6-month recurrence in patients with myocardial infarction. Another study found that although hostility is related to lower social support, when it is available, it provides fewer physiological benefits to hostile persons.

Intervention

Intervention for hostility can take one of two forms. Pharmacological interventions focus on blocking the impact of key physiological mechanisms on cardiac targets. Behavioral interventions focus on altering the cognitive, behavioral, and emotional concomitants of hostility as a way to reduce the frequency and

intensity with which the physiological pathways are mobilized.

Pharmacological

β -adrenergic blocking drugs block the impact of increased sympathetic tone on the heart, triggered by hostility, and thereby reduce the hemodynamic response that may lead to plaque disruption. With this therapy, hostile individuals may construe the stressor as threatening, but the concomitant sympathetic arousal has little, if any, impact on heart rate or blood pressure. Aspirin has antiplatelet properties and thus may prevent sympathetically induced platelet aggregation that leads to thrombus formation. Estrogen therapy in women with existing coronary disease does not weaken the ability of hostility to predict recurrent coronary events.

Behavioral

Effective behavioral interventions for hostility must begin with the development of sensitivity to signs and symptoms of hostility in the individual him- or herself. This is a difficult task because hostility tends to be well rationalized, based upon real or perceived insults from the social environment. Interventions are most effective when they focus on the development of skills and competencies in all of the domains of hostility. Relaxation therapies help the individual to develop the skill to switch from sympathetic arousal to parasympathetic relaxation. Assertiveness training can help individuals to replace hostile interactional styles with less arousing and more effective alternatives. Cognitive therapy can help individuals to identify cognitions, such as blaming others, that are associated with arousal and to replace them with alternatives that are more rational and less arousing. The development of efficacy in controlling emotional arousal in response to environmental challenges has the effect of improving self-esteem, improving interpersonal effectiveness, and producing more positive feedback from the social environment. Progressively, as skills develop, the enhanced interpersonal effectiveness can challenge core cynical and mistrusting beliefs.

Glossary

*Hypothalamic-
pituitary-
adrenal (HPA)*

The HPA system is one of the major two neuroendocrine stress response systems of the body. Stress stimulates the release of the hypothalamic neurohormonal peptides, corticotropin releasing hormone and arginine vasopressin, that stimulate secretion of the pituitary adrenocorticotrophic hormone (ACTH), which in turn stimulates the secretion of adrenal corticosteroids. In addition to its role in the stress response, the HPA system plays a role in and serves as a biomarker of mental disorders and especially depression and posttraumatic stress disorder (PTSD).

Introduction

The study of the neuroendocrinology of posttraumatic stress disorder (PTSD) has presented an interesting paradox – some of the alterations described have not historically been associated with pathological processes. In particular, initial observations of low cortisol levels in a disorder precipitated by extreme stress directly contradicted the emerging and popular formulation of hormonal responses to stress, the glucocorticoid cascade hypothesis, which posited that stress-related psychopathology involves hypercortisolism as either a cause or consequence of disorder. It is now clear that insufficient glucocorticoid signaling

may produce detrimental consequences as robust as those associated with glucocorticoid toxicity.

With respect to PTSD, the majority of studies demonstrate alterations consistent with an enhanced negative feedback inhibition of cortisol on the pituitary and/or an overall hyperreactivity of other target tissues (adrenal gland and hypothalamus). Findings of low cortisol and increased reactivity of the pituitary in PTSD are also consistent with reduced adrenal output, although it is more difficult to fully explain cortisol elevations in response to stress and neuroendocrine challenge with this model.

Insofar as there have been discrepancies in the literature with regard to basal hormone levels, investigators more recently theorized that models of enhanced negative feedback, increased hypothalamic-pituitary-adrenal (HPA) reactivity, and reduced adrenal capacity may explain different facets of the neuroendocrinology of PTSD, including preexisting risk factors that may be related to certain types of early experiences, at least in certain people who develop PTSD. Notwithstanding that some aspects of HPA alterations may predate exposure to a traumatic event that precipitates PTSD, alterations associated with enhanced negative feedback inhibition also appear to develop over time in response to the complex biological demands of extreme trauma and its aftermath. Moreover, the findings of increased HPA reactivity may sometimes reflect a more nonspecific response to ongoing environmental challenges associated with having chronic PTSD. Certainly the absence of cortisol alterations in some studies imply that the alterations associated with low cortisol and enhanced negative feedback are present only in a biological subtype of PTSD. The observations in the aggregate, and the alternative models of pathology or adaptation suggested by them, must be clearly understood when using neuroendocrine data in PTSD to identify targets for drug development.

Basal Cortisol Levels in Posttraumatic Stress Disorder

The majority of the evidence supports the conclusion that cortisol levels in PTSD are different from those observed in acute and chronic stress and in major depression; that is, they are lower, rather than higher, compared to normal. However, it should be noted that there have been many reports that failed to observe low cortisol levels and (although fewer) that have reported cortisol increases in PTSD. This discrepancy may be due to the fact that basal alterations of cortisol in PTSD are subtle. That is, even

when cortisol is reported to be significantly lower in PTSD, levels fall within the normal endocrinological range. There are numerous other sources of potential variability in such studies related to the selection of subjects and comparison groups, adequate sample size, and inclusion/exclusion criteria, as well as considerations that are specific to the methods of collecting and assaying cortisol levels, that can explain the discrepancies in the findings. However, the simplest explanation for the disparate observations is that cortisol levels may not represent stable trait markers and are likely to fluctuate, making it difficult to consistently observe group differences.

There is better agreement in studies of circadian rhythmicity of cortisol in PTSD, although these are fewer in numbers. The advantage of these studies is that plasma samples can be obtained continuously throughout the 24-h cycle under controlled conditions. Thus, not only is it possible to confirm overall mean cortisol release but also to determine the times of day at which alterations are most likely to be present and note changes in circadian rhythm parameters. Indeed, it appears that the major difference between PTSD and non-PTSD groups is that cortisol levels are lower in the late night and remain lower for a longer period of time in PTSD during hours when subjects are normally sleeping.

Even in cases in which there is failure to find group differences in cortisol levels, there are often correlations within the PTSD group with indices of PTSD symptom severity or trauma exposure. Most often, investigators have reported negative correlations between cortisol levels (particularly integrated mean 24-h cortisol levels) and PTSD symptoms in combat veterans. Low cortisol levels have also been negatively correlated with duration since trauma, implying that low cortisol is associated with early traumatization. In fact, in some recent studies, cortisol levels were inversely related to childhood traumatic experiences, including emotional abuse, even in the absence of PTSD.

Cortisol levels have also been correlated with findings from brain imaging studies in PTSD. In one report, there was a positive relationship between cortisol levels and hippocampal acetylaspartate (NAA), a marker of cell atrophy presumed to reflect changes in neuronal density or metabolism, in subjects with PTSD, suggesting that, rather than having neurotoxic effects, cortisol levels in PTSD may have a trophic effect on the hippocampus. Similarly, cortisol levels in PTSD were negatively correlated with medial temporal lobe perfusion, whereas anterior cingulate perfusion and cortisol levels were positively correlated in PTSD but negatively correlated in trauma survivors without PTSD. These inverse correlations may result from an augmented negative hippocampal effect secondary to increased sensitivity of brain

glucocorticoid receptors, which would account for the inverse correlation in PTSD despite equal cortisol levels in both the PTSD and non-PTSD groups. On the other hand, the positive correlation between regional cerebral blood flow in the frontocingulate transitional cortex and cortisol levels in PTSD may reflect unsuccessful attempts of the frontocingulate transitional cortex to terminate the stress response, which has also been linked with low cortisol.

Cortisol may be related to specific or state-dependent features of the disorder, such as comorbid depression or the time course of the disorder. There is a long and rich tradition in psychosomatic medicine underscoring the importance of examining intrapsychic correlates of individual differences in cortisol levels in PTSD, reflecting emotional arousal and opposing antiarousal disengagement defense mechanisms or other coping styles. Finally, recent evidence also suggests that cortisol levels further decrease over time and in old age in trauma survivors.

Cortisol Levels in Response to Stress

Although cortisol levels may be lower at baseline, they may actually be elevated in PTSD relative to comparison subjects when challenged by physiological or psychological stressors. In particular, subjects with PTSD appear to show more anticipatory anxiety to laboratory stressors, which is reflected by increased cortisol levels. These studies provide at least some evidence that the adrenal is capable of producing ample cortisol levels at baseline and in response to stress. In fact, transient increases in cortisol levels are consistent with the notion of a more generalized HPA axis reactivity in PTSD, as reflected by enhanced negative feedback inhibition.

Basal Corticotropin Releasing Hormone and Adrenocorticotrophic Hormone Levels in Posttraumatic Stress Disorder

Interestingly, all published reports examining the concentration of corticotropin releasing hormone (CRH) in cerebrospinal fluid (CSF) in PTSD have concluded that levels of this peptide are increased in PTSD. The assessment of CSF CRH does not necessarily provide a good estimate of hypothalamic CRH release but, rather, an estimate of both the hypothalamic and extra-hypothalamic release of this neuropeptide. Nonetheless, that there is increased CRH release is somewhat of a paradox considering the lower cortisol levels. With respect to adrenocorticotrophic hormone (ACTH), the majority of studies have reported no detectable differences in ACTH levels between PTSD and comparison subjects even when cortisol levels obtained from the same sample were found to be significantly lower.

Lower cortisol levels in the face of normal ACTH levels can reflect a relatively decreased adrenal output. Yet, under circumstances of classic adrenal insufficiency, there is usually increased ACTH release compared to normal levels. Thus, in PTSD, there may be an additional component of feedback on the pituitary acting to depress ACTH levels so that they appear normal rather than elevated. Indeed, elevations in ACTH are expected not only from a reduced adrenal output but also from increased CRH stimulation. On the other hand, the adrenal output in PTSD may be relatively decreased but not enough to substantially affect ACTH levels. In any event, the normal ACTH levels in PTSD in the context of the other findings suggest a more complex model of the regulatory influences on the pituitary in this disorder than reduced adrenal insufficiency.

Glucocorticoid Receptors in Posttraumatic Stress Disorder

Type II glucocorticoid receptors (GRs) are expressed in ACTH- and CRH-producing neurons of the pituitary, hypothalamus, and hippocampus and mediate most systemic glucocorticoid effects, particularly those related to stress responsiveness. Low circulating levels of a hormone or neurotransmitter can result in increased numbers of available GRs to improve response capacity and facilitate homeostasis. However, alterations in the number and sensitivity of both type I (mineralocorticoid) and type II GRs can also significantly influence HPA axis activity and, in particular, can regulate hormone levels by mediating the strength of negative feedback. In PTSD, there is evidence for both an increased number of GRs (measured in lymphocytes) and increased responsiveness of the GR.

Observations regarding the cellular immune response in PTSD are also consistent with enhanced GR responsiveness in the periphery, as indicated by increased beclomethasone-induced vasoconstriction and enhanced delayed-type hypersensitivity of skin test responses. Because immune responses, like endocrine ones, can be multiply regulated, these studies provide only indirect evidence of GR responsiveness. However, when considered in the context of the observation that PTSD patients showed an increased expression of the receptors in all lymphocyte subpopulations, despite a relatively lower quantity of intracellular GRs, as determined by flow cytometry, and in the face of lower ambient cortisol levels, the findings more convincingly support an enhanced sensitivity of the GRs to glucocorticoids. Furthermore, there appears to be an absence of alterations of the mineralocorticoid receptor in PTSD, as investigated by examining the cortisol and ACTH response to spiro-lactone following CRH stimulation.

With respect to increased glucocorticoid responsiveness, this was recently determined using an *in vitro* paradigm in which mononuclear leukocytes were incubated with a series of concentrations of dexamethasone (DEX) to determine the rate of inhibition of lysozyme activity. Subjects with PTSD showed evidence of a greater sensitivity to glucocorticoids as reflected by a significantly lower mean lysozyme median inhibitory concentration of DEX (IC_{50-DEX} ; in nanomoles per liter). The lysozyme IC_{50-DEX} was significantly correlated with age at exposure to the first traumatic event in subjects with PTSD. The number of cytosolic GRs was correlated with age at exposure to the focal traumatic event.

The Dexamethasone Suppression Test in Posttraumatic Stress Disorder

In contrast to observations regarding ambient cortisol levels, results using the dexamethasone suppression test (DST) present a more consistent view of reduced cortisol suppression in response to DEX administration. The DST provides a direct test of the effects of GR activation in the pituitary on ACTH secretion, and cortisol levels following DEX administration are thus interpreted as an estimate of the strength of negative feedback inhibition, provided that the adrenal response to ACTH is not altered. Using 0.50 mg DEX, most investigators have found a more dramatic reduction in plasma cortisol levels. This exaggerated cortisol suppression in response to DEX has been observed in PTSD related to people with combat exposure, survivors of childhood sexual abuse, Holocaust survivors, children exposed to disaster, women exposed to domestic violence, and mixed groups of trauma survivors.

The Metyrapone Stimulation Test

Metyrapone prevents adrenal steroidogenesis by blocking the conversion of 11-deoxycortisol to cortisol, thereby unmasking the pituitary gland from the influences of negative feedback inhibition. If a sufficiently high dose of metyrapone is used, such that an almost complete suppression of cortisol is achieved, this allows a direct examination of pituitary release of ACTH without the potentially confounding effects of differing ambient cortisol levels. When metyrapone is administered in the morning when HPA axis activity is relatively high, maximal pituitary activity can be achieved, facilitating an evaluation of group differences in pituitary capability. The administration of 2.5 mg metyrapone in the morning resulted in a similar and almost complete reduction in cortisol levels in both PTSD and normal subjects (i.e., removal of negative feedback inhibition) but in a higher

increase in ACTH and 11-deoxycortisol in combat Vietnam veterans with PTSD, compared to nonexposed subjects. In the context of low cortisol levels and increased CSF CRH levels, the findings supported the hypothesis of a stronger negative feedback inhibition in PTSD. Both pituitary and adrenal insufficiency are not likely to result in an increased ACTH response to the removal of negative feedback inhibition because the former is associated with an attenuated ACTH response and reduced adrenal output would not necessarily affect the ACTH response. To the extent that ambient cortisol levels are lower than normal, an increased ACTH response following the removal of negative feedback inhibition implies that, when negative feedback is intact, it is strong enough to inhibit ACTH and cortisol. The increased ACTH response is most easily explained by increased suprapituitary activation; however, a sufficiently strong negative feedback inhibition would account for the augmented ACTH response even in the absence of hypothalamic CRH hypersecretion.

Evidence of increased ACTH was not observed when a lower dose of metyrapone was used, administered over a 3-h period at night (750 mg at 7:00 a.m. and 10:00 a.m.). However, interestingly, the manipulation produced a more robust suppression of cortisol in comparison subjects. Using a similar methodology, the effects of metyrapone was used to evaluate CRH effects on sleep. ACTH and cortisol levels were increased in the PTSD group relative to the controls the next morning, suggesting that the same dose of metyrapone did not produce the same degree of adrenal suppression of cortisol synthesis. Under these conditions, it is difficult to evaluate the true effect on ACTH and 11-deoxycortisol, which depends on achieving complete cortisol suppression, or at least the same degree of cortisol suppression, in the two groups. The endocrine response to metyrapone in this study do not support the model of reduced adrenal capacity because this would have yielded a large ratio of ACTH-to-cortisol release, yet the mean ACTH/cortisol ratio prior to metyrapone was no different in the PTSD subjects and the controls. On the other hand, the mean ACTH/cortisol ratio postmetyrapone was lower, although not significantly, suggesting, if anything, an exaggerated negative feedback rather than reduced adrenal capacity.

The Corticotropin Releasing Hormone Challenge Test and Adrenocorticotrophic Hormone Stimulation Test in Posttraumatic Stress Disorder

The infusion of exogenous CRH increases ACTH levels and provides a test of pituitary sensitivity. A blunted ACTH is classically thought to reflect a

reduced sensitivity of the pituitary to CRH, reflecting a downregulation of pituitary CRH receptors secondary to CRH hypersecretion. The results of studies in PTSD subjects using this challenge have also been mixed. Some studies have demonstrated a blunted ACTH response to PTSD; however, insofar as this blunting did not occur in the presence of hypercortisolism, as in depression, the attenuated ACTH response may reflect an increased negative feedback inhibition of the pituitary secondary to increased GR number or sensitivity. This explanation supports the idea of CRH hypersecretion in PTSD and explains the pituitary desensitization and resultant lack of hypercortisolism as arising from a stronger negative feedback inhibition. An augmented ACTH response to CRH has also been reported, which the authors interpreted as reflecting increased reactivity of the pituitary, although here too there was no evidence for increased cortisol levels.

Findings of Cortisol in the Acute Aftermath of Trauma

Recent data provided some support for the idea that low cortisol levels may be an early predictor of PTSD rather than a consequence of this condition. Low cortisol levels in the immediate aftermath of a motor vehicle accident predicted the development of PTSD in a group of accident victims consecutively presenting in an emergency room in two studies. In a sample of people who survived a natural disaster, cortisol levels were similarly found to be lowest in those with highest PTSD scores at 1 month posttrauma; however cortisol levels were not predictive of symptoms at 1 year. In the acute aftermath of rape, low cortisol levels were associated with prior rape or assault, themselves risk factors for PTSD, but not with the development of PTSD *per se*.

These findings imply that cortisol levels might have been lower in trauma survivors who subsequently developed PTSD even before their exposure to trauma and might therefore represent a preexisting risk factor. Consistent with this, low 24-h urinary cortisol levels in adult children of Holocaust survivors were specifically associated with the risk factor of parental PTSD. Interestingly, the risk factor of parental PTSD in offspring of Holocaust survivors was also associated with an increased incidence of traumatic childhood antecedents. In this study, both the presence of subject-rated parental PTSD and scores reflecting childhood emotional abuse were associated with low cortisol levels in offspring. Thus, it may be that low cortisol levels occur in those who have experienced an adverse event early in life and then remain different from those not exposed to early adversity. Although there might reasonably be HPA axis

fluctuations in the aftermath of stress, and even differences in the magnitude of such responses compared to those not exposed to trauma early in life, HPA parameters would subsequently recover to their (abnormal) prestress baseline.

Low cortisol levels may impede the process of biological recovery from stress, resulting in a cascade of alterations that lead to intrusive recollections of the event, avoidance of reminders of the event, and symptoms of hyperarousal. This failure may represent an alternative trajectory to the normal process of adaptation and recovery after a traumatic event.

One of the most compelling lines of evidence supporting the hypothesis that lower cortisol levels may be an important pathway to the development of PTSD symptoms are the results of studies showing that the administration of stress doses of hydrocortisone prevents the development of PTSD and traumatic memories and attenuate these symptoms once present. These findings support the idea that low cortisol levels may facilitate the development of PTSD in response to an overwhelming biological demand, at least in some circumstances.

Conclusion

Cortisol levels are most often found to be lower than normal in PTSD subjects, but can also be similar to or greater than those in comparison subjects. Findings of changes in circadian rhythm suggest that there may be regulatory influences that result in a greater dynamic range of cortisol release over the diurnal cycle in PTSD. Thus, although cortisol levels may be generally lower, the adrenal gland is certainly capable of producing adequate amounts of cortisol in response to challenge.

The model of enhanced negative feedback inhibition is compatible with the idea that there may be transient elevations in cortisol, but suggests that, when present, these increases are shorter-lived due to a more efficient containment of ACTH release as a result of enhanced GR activation. An increased negative feedback inhibition results in reduced cortisol levels under ambient conditions. In contrast to other models of endocrinopathy, which identify specific and usually singular primary alterations in endocrine organs and/or regulation, the model of enhanced negative feedback inhibition in PTSD is in large part descriptive and currently offers little explanation of why some individuals show such alterations of the HPA axis following exposure to traumatic experiences and others do not.

The wide range of observations observed in the neuroendocrinology of PTSD underscores the important observation that HPA response patterns in PTSD are fundamentally in the normal range and do not

reflect endocrinopathy. In endocrinological disorders, in which there is usually a lesion in one or more target tissue or biosynthetic pathway, endocrine methods can usually isolate the problem with the appropriate tests and then obtain rather consistent results. In psychiatric disorders, neuroendocrine alterations may be subtle, and therefore, when using standard endocrine tools to examine these alterations, there is a high probability of failing to observe all the alterations consistent with a neuroendocrine explanation of the pathology in tandem or of obtaining disparate results within the same patient group owing to a stronger compensation or reregulation of the HPA axis following challenge.

The next generation studies should aim to apply more rigorous tests of neuroendocrinology of PTSD based on the appropriate developmental issues and in consideration of the longitudinal course of the disorder and the individual differences that affect these processes. No doubt such studies will require a closer examination of a wide range of biological responses, including the cellular and molecular mechanisms involved in adaptation to stress, and an understanding of the relationship between the endocrine findings and other identified biological alterations in PTSD.

Calamity

Hurricane Katrina

Methodological Issues

Impact on Human Populations

Glossary

Chaos theory A scientific paradigm that suggests that chaos and complexity are inherent to explaining phenomena; it aids in the understanding of how organizations respond, adapt, change, function, and renew.

Direct-contact victims

Emergency and rescue workers who searched for survivors and dead bodies, as well as morgue personnel.

Disaster mental health

A competency-based intervention model, based on disaster-related psychopathology, that addresses a community's mental health needs.

First-responders

All emergency personnel that aid in the immediate aftermath of a disaster, such as police, firefighters, rescue workers, medical staff, and special response units. The costliest hurricane to hit the United States prior to Hurricane Katrina; it caused \$44 billion in damage in 1992.

Hurricane Andrew

Mass-casualty event

An event that involves multidimensional stressors that may result in differential patterns of posttraumatic reactions, both short and long term.

<i>Northeast quadrant</i>	The storm quadrant with the strongest winds and rain (because hurricanes circulate counterclockwise). In Hurricane Katrina, this meant that the areas east of New Orleans, for 160 miles, received the brunt of the storm's wrath.
<i>Self-efficacy</i>	An individual's belief that his or her actions and behavior will produce the desired outcomes; coined by personality theorist Albert Bandura.

Calamity

Without a doubt, Hurricane Katrina (August 29, 2005) was the most destructive and costly natural disaster in U.S. history. Months after the storm, the total destruction, including the human toll, is still being calculated. Perhaps as a key indicator of the enormity of the devastation, 6 months after the disaster news accounts on every aspect of the tragedy still appear each night on the national news networks, the number of deaths are provided as an estimate, and over 100 of the deceased victims have not yet been identified. The numbers, to date, allow an appreciation of the impact:

- Deaths: ~1500, either during or immediately after the storm.
- Homeless residents: 800,000.
- Victims left unemployed: ~550,000.
- Displaced people: 2 million.
- Homes destroyed: 350,000.
- Penetration of the storm surge along the Louisiana, Mississippi, and Alabama coast was measured in miles not feet.
- Property losses: ~\$35 billion.
- Estimates for reclamation: 2 years to clear 22 million tons of waste and debris.
- Small businesses not in operation: 50%.
- Cars submerged under water: 200,000.
- Residents of the greater New Orleans area who may have to relocate permanently: ~75%.
- Area of the city of New Orleans that was flooded: ~70%.
- Evacuees separated from their pets: ~80%.
- Estimate of total economic costs and damage: varies widely, but will probably reach \$200 billion.

Hurricane Katrina

Hurricane Katrina was both an immensely powerful and a large storm. Initial forecasts estimated winds of 145 mph at landfall, but revised figures from the National Hurricane Center in Miami reported maximum sustained winds of approximately 125 mph; officially, the storm was a high category 3 hurricane.

Hurricane-force winds (>74 mph) extended 160 miles out from the eye of the storm. Unbelievably, the city of Waveland, Mississippi, was struck by a 28-ft storm surge. Several hours after the eye of the storm passed New Orleans, the levee system that protected the city was either breached or undermined in three strategic areas; within hours, approximately two-thirds of the city was submerged under up to 12 ft of water. Many residents drowned, and thousands sought higher ground.

The initial governmental response, particularly that of the Federal Emergency Management Agency (FEMA), can be regarded as a complete debacle; however, many regular citizens, volunteers, and health-care personnel extended themselves to save lives. Unfortunately, most residents were left to fend for themselves for almost a week before basic necessities arrived. The result was untold human suffering. Small coastal cities along the gulf coast from Port Sulphur, Louisiana, to Mobile, Alabama, were hard hit by high winds, torrential rain, and a destructive storm surge; some small towns on the Mississippi and Alabama coast were literally wiped off the map.

Outside of the impact area, the country felt the residual impact of the calamity: anger over government malaise, a sense of national shame, and high energy prices. Undoubtedly, the social consciousness of the public was severely tested, particularly with regard to the racial issues and poverty that were brought to the forefront in the aftermath of the storm. In this regard, Hurricane Katrina will always be considered both a natural and human-made disaster.

Methodological Issues

Although the United States suffered several devastating natural disasters in its history (e.g., the San Francisco earthquake, the Galveston hurricane, and Mississippi River floods), the calamity of Hurricane Katrina has no precedent with regard to human suffering, social displacement, structural damage, and financial cost. Summarily, a continuous stretch of 200 miles of the U.S. coast was adversely impacted, including a population of approximately 3.6 million residents. At the time of this writing (6 months post-disaster), there is limited empirical research on the storm, although many articles have appeared in general media publications. Because I am a disaster researcher, I can attest to the fact that there are a plethora of research studies underway, particularly at universities in the New Orleans area.

Researchers should be cautioned about several unique features of investigating this disaster. First and foremost, Hurricane Katrina was not a unitary impact event; that is, from a methodological

perspective, not all regions (and populations) were impacted in the same manner or experienced the same level or type of disaster. For example, New Orleans basically experienced a flood event and was not greatly impacted by hurricane winds (the city lay west of the eye of the storm). However, smaller coastal communities to the east of the eye (coastal Louisiana, Mississippi, and Alabama) felt the full brunt of hurricane-force winds and devastating storm surge. Some residents had recoverable property damage, whereas others were completely wiped out. Some residents evacuated to safety, whereas others rode out the storm. Many victims evacuated temporarily, whereas others were displaced to cities throughout the United States and many in this latter group will probably not return to their home areas. Moreover, there was a great disparity in the amount of governmental support and financial assistance that individuals received, commensurate with the amount of damage, need for shelter, and sustenance needs. Therefore, researchers need to be cognizant of these factors when studying select populations and be aware that not everyone experienced Hurricane Katrina in the same way. Green reviewed some of the difficulties encountered in designing sound disaster research studies, and several investigators have considered the heterogeneous nature of studying the effects of hurricanes on different cohort groups. Furthermore, due to the overwhelming nature of the disaster and its aftermath, Hurricane Katrina, for many victims, was a multiple traumatic loss: that is, a loss of loved ones, pets, residence, job, security, and the future.

Impact on Human Populations

Flooding

Much of New Orleans was severely flooded due to the failure of levee structures. Both natural and human-made disasters can result in flooding, for example, the Buffalo Creek dam collapse in 1972 and the Great Midwest Mississippi floods in 1993. The effects of extensive flooding were studied in the aftermath of Hurricane Floyd, which struck North Carolina in 1999. Emotional exhaustion, grief reactions and depression, posttraumatic stress disorder (PTSD) symptomatology, and somatic complaints were identified as the major sequela in several studies. The aged seemed to be the most affected.

Health Issues

The health consequences of natural disasters have been a major research area. For example, in the 1983 South Australian bush fires, Japan's 1995

Hanshin-Awaji earthquake, and California's 1994 Northridge earthquake, impacted populations were found to be vulnerable to a host of medical maladies, particularly stress-related conditions such as hypertension, gastrointestinal disorders, diabetes, and mental illness. Non-stress-related conditions were typically not affected. Most conditions were found to improve within 15 months postdisaster. Investigators have reported on the impact of immunological changes after natural disasters and found that adaptive coping to stress effects mediated immunological responses in affected populations.

Mental Health Symptoms

Psychiatric morbidity, particularly stress-related conditions, have been extensively studied in both natural and human-made disasters. Specifically, PTSD, depression, and substance abuse disorders have been reported to significantly increase following large-scale disasters. Researchers caution that acute stress disorder is prognostically important as a marker for the development of moderate or full PTSD symptoms in the long term. One study on mental health symptomatology following Hurricane Andrew reported that 36% of the sample had PTSD, 30% experienced major depression, and 20% showed signs of anxiety disorders. In fact, 56% had significant symptoms persisting beyond 6 months posthurricane. Due to the high prevalence of mental health problems experienced in the wake of hurricanes, researchers point to the critical importance of coping self-efficacy perceptions as a mediator between acute stress response and long-term distress following natural disasters.

Because geographical relocation was a major aspect of the Katrina disaster, it should be an area of particular research focus. Prior studies in this area concluded that displaced individuals in natural disasters exhibit more intense levels of psychopathology, particularly depression. Perhaps, this is the result of unresolved grief on the part of victims who were not only relocated but also lost their homes and needed to start over elsewhere. Moreover, in a study of family life following Hurricane Hugo in 1989, researchers found the divorce rate increased. In this regard, there have been recent media ad campaigns across the impacted Gulf Coast areas that address post-Hurricane Katrina family stress issues such as child and wife abuse.

Recovery Issues

There are a number of governmental recovery plans in place across the Gulf Coast, although their implementation seems to be progressing slowly. Research following Hurricane Andrew in 1992

indicated that disruption during rebuilding phases contributed to the exacerbation of mental health symptoms. In recent years, social scientists have advocated disaster mental health-planning initiatives via national organizations such as the American Psychological Association to address preparedness planning, mitigation, agency coordination, and community resource development. Particularly in the context of the complexity of disasters, interagency cooperation and coordination are crucial to meeting the social and psychological needs of victims posthurricane.

By all accounts, the governmental response in the immediate aftermath of Katrina and the subsequent lethargic recovery efforts can only be described as appalling. This unfortunate state of affairs can only impede individual and collective efforts at achieving some sense of normality among the affected population. Instead, much of the goodwill and recovery assistance to the affected population came from local church groups and organizations such as the Red Cross. Indeed, this is also what occurred after the double hit of Hurricanes Erin and Opal in Pensacola, Florida.

Special Populations

It is incumbent that researchers pay particular attention to population groups such as the aged, health-delivery workers, children, the disabled, first-responders, and impoverished citizens. Unique populations cope with stressors in diverse ways, and stress reactions tend to be heterogeneous. This was the finding of a study on children following the Oklahoma City bombing. Furthermore, the critical function of denial in both child and adult populations has received theoretical support in prior research studies. Last, there has been much media attention given to race and poverty issues in the aftermath of Katrina; this will be an important factor in ongoing research, although recent research findings on this issue are equivocal.

Glossary

11 β -Hydroxysteroid dehydrogenase (11 β -HSD) An enzyme that catalyzes the interconversion of active cortisol (corticosterone in rats and mice) and inert cortisone (11-dehydrocorticosterone).

11 β -HSD type 1 (11 β -HSD1) An isozyme that predominantly catalyzes the reduction of inert cortisone to active cortisol in intact cells and organs.

11 β -HSD type 2 (11 β -HSD2) An isozyme that catalyzes the rapid dehydrogenation of active cortisol to inert cortisone.

Aromatase The enzyme that catalyzes the conversion of androgens to estrogens.

Carbenoxolone A nonselective 11 β -HSD inhibitor.

Cushing's syndrome The generic description of the phenotype observed with circulating glucocorticoid excess, due either to endogenous overproduction of cortisol or adrenocorticotrophic hormone (ACTH) or to exogenous pharmacotherapy.

Glucocorticoid receptor (GR) Intracellular receptor for active cortisol.

Intracrine

The process whereby intracellular enzymic transformations of steroids alter their access to nuclear receptors.

Metabolic syndrome

The co-association of risk factors for atheromatous disease (insulin resistance, type 2 diabetes, dyslipidemia, and hypertension) and abdominal (visceral) obesity.

Mineralocorticoid receptor (MR)

Intracellular receptor for active cortisol, selectivity for aldosterone *in vivo* generated by 11 β -HSD2.

Syndrome of apparent mineralocorticoid excess

A congenital syndrome of hypertension, hypernatremia, and hypokalemia due to inappropriate MR activation by glucocorticoids because of deleterious mutations of the 11 β -HSD type 2 gene and hence lack of the enzyme in the kidney.

Definition: 11 β -Hydroxysteroid Dehydrogenase

Elevated plasma cortisol or glucocorticoid pharmacotherapy has myriad adverse effects ranging from obesity, diabetes, and hypertension to depression and memory impairments. Glucocorticoid action is classically believed to be determined by the product of circulating glucocorticoid levels and the tissue density of corticosteroid receptors (GR and MR). However, recent discoveries suggest a key role for local enzymic tissue metabolism of glucocorticoids in determining receptor activation. The main enzymes involved are the 11 β -hydroxysteroid dehydrogenases (11 β -HSDs). These catalyze the interconversion of active cortisol (in humans and most mammals) and corticosterone (in rats and mice) and inert 11-keto forms (cortisone, 11-dehydrocorticosterone) ([Figure 1](#)). The roles of these enzymes in determining glucocorticoid actions in the central nervous system (CNS) and periphery are now becoming apparent.

The Mineralocorticoid Receptor Paradox

Purified MR binds aldosterone, cortisol, and corticosterone with equal and high affinity *in vitro*, but *in vivo*

Figure 1 11 β -Hydroxysteroid dehydrogenases. Type 1 acts as a ketoreductase, regenerating active cortisol (corticosterone), whereas type 2 acts as a dehydrogenase, rapidly inactivating these physiological glucocorticoids.

only aldosterone binds to MR in the kidney, although there is much more glucocorticoid in the circulation. In resolution of this paradox, in 1988 groups in Edinburgh and Melbourne reported that 11 β -HSD was a prereceptor enzymic mechanism that bestowed aldosterone selectivity on the intrinsically nonselective MR *in vivo*. The 11 β -HSD activity associated with MR in the distal nephron acted as a dehydrogenase, rapidly inactivating physiological glucocorticoids (cortisol, corticosterone) to their inert 11-keto forms. Such 11 β -HSD activity forms an intracellular barrier to glucocorticoids, preventing the occupation of MR. When the enzyme is congenitally deficient in the syndrome of apparent mineralocorticoid excess or is inhibited by liquorice, glucocorticoids inappropriately access MR, causing sodium retention, hypertension, and hypokalemia. Although an NADP(H)-associated 11 β -HSD activity (now called 11 β -HSD1) and its encoding cDNA were isolated from rat liver by Monder and colleagues in the mid-1980s, this was shown not to be responsible for renal MR selectivity: its encoding gene HSD11B1 was intact in patients with the syndrome. Subsequently a second 11 β -HSD isozyme (11 β -HSD2) was cloned from the kidney and placenta in a variety of species. This isozyme is a high-affinity 11 β -dehydrogenase, which uses NAD as cofactor and is highly expressed in the distal nephron and placenta. Patients with the syndrome of apparent mineralocorticoid excess were homozygous or compound heterozygous for deleterious mutations in the HSD11B2 gene, and 11 β -HSD2 knockout mice faithfully recapitulated the syndrome. This work underlined the fundamental principle that steroid access to nuclear receptors *in vivo* is regulated by prereceptor metabolism. Other examples include 5- and 5'-monodeiodinases (thyroid hormone receptors), 5 α -reductase (androgen receptor), and aromatase (estrogen receptors).

11 β -Hydroxysteroid Dehydrogenase Type 2 in the Adult Central Nervous System

Although the vast majority of MR in the CNS are nonselective and bind glucocorticoids (cortisol,

corticosterone) *in vivo*, it is anticipated that any selective effects of aldosterone in the CNS will require MR gated by local 11 β -HSD2. In this regard, aldosterone mediates the central regulation of blood pressure and salt appetite. Thus, aldosterone infused intracerebroventricularly (ICV) elevates blood pressure in the rat, whereas the same dose given peripherally is ineffective, demonstrating a specific central action. Corticosterone ICV does not reproduce this action, and indeed antagonizes aldosterone hypertension. Similarly, aldosterone exerts central actions on salt appetite that cannot be reproduced by corticosterone. 11 β -HSD2 action in the CNS is therefore inferred. This is supported by ICV infusion of the 11 β -HSD inhibitor carbenoxolone, which increases blood pressure in the rat, an effect reversed by an MR antagonist, suggesting central 11 β -HSD2 prevents access of glucocorticoids to central MR. Although 11 β -HSD2 mRNA is only found in a few discrete sites in the adult rat brain, these loci also express MR and are believed to underlie the selective central effects of aldosterone to increase blood pressure (nucleus tractus solitarius, NTS), and modulate salt appetite (ventromedial hypothalamus, subcommissural organ, and central nucleus of the amygdala). In the mouse there is an even more limited distribution of 11 β -HSD2, with expression confined to the NTS. 11 β -HSD2 was not found in the human forebrain, although the brain stem has not been investigated. Thus, there is very little 11 β -HSD2 in the adult brain, located appropriately for the few CNS actions specifically ascribed to this hormone.

11 β -Hydroxysteroid Dehydrogenase Type 2 in the Developing Central Nervous System

Prenatal glucocorticoid administration reduces brain weight at birth; delays the maturation of neurons, glia, and cerebral vasculature; and retards CNS myelination. Given such widespread effects, it is unsurprising that GR and MR are highly expressed in the developing brain. However, whether these receptors are occupied by endogenous glucocorticoids until late gestation is uncertain because there is also plentiful 11 β -HSD2 in the CNS at midgestation in rodents and humans. This presumably functions to protect vulnerable developing cells from premature glucocorticoid action. Strikingly, 11 β -HSD2 expression is dramatically switched off in a CNS at the end of midgestation, coinciding with the terminal stage of brain nucleus development. This appears to be an exquisitely timed system of cellular protection from circulating glucocorticoids.

11 β -Hydroxysteroid Dehydrogenase Type 2 and Fetal Programming

Human epidemiological studies show that low birth weight at term is associated with an increased later occurrence of cardiovascular (hypertension and ischemic heart disease) and metabolic disorders (type 2 diabetes) in adult life. In rodents, sheep, and humans, excessive exposure to glucocorticoids during gestation, either bypassing of fetoplacental 11 β -HSD2 with nonsubstrate glucocorticoid such as dexamethasone or using 11 β -HSD inhibitors such as carbenoxolone, reduces birth weight. Although in such models, the weight deficit is regained soon after birth, the adult offspring show increased blood pressure and serum insulin and glucose levels. These effects are underpinned by an increased tissue sensitivity to glucocorticoids via increased GR density in key metabolic loci such as the liver and visceral adipose tissue depots.

Programming the Hypothalamic-Pituitary-Adrenal Axis and Behavior

Prenatal 11 β -HSD2 inhibition or bypass with the nonsubstrate dexamethasone permanently increases basal plasma corticosterone levels in the offspring in rats. The density of GR and MR in the hippocampus are reduced in this model, which is anticipated to reduce hypothalamic-pituitary-adrenal (HPA) axis feedback sensitivity. Moreover the glucocorticoid excess may drive, at least in part, the hypertension and hyperglycemia observed in such prenatal programming models. Maternal undernutrition also lowers placental 11 β -HSD2 and alters adult offspring metabolic, cardiovascular, and HPA axis function, suggesting that HPA programming may be a common outcome of prenatal environmental challenge. Overexposure to glucocorticoids *in utero* also leads to alterations in adult behavior to produce a phenotype reminiscent of anxiety. Prenatal glucocorticoid exposure also affects the developing dopaminergic system with clear implications for proposed developmental contributions to schizo-affective, attention-deficit hyperactivity and extrapyramidal disorders. Mechanistically, prenatal dexamethasone or 11 β -HSD inhibition increases corticotropin-releasing hormone (CRH) mRNA levels specifically in the central nucleus of the amygdala, a key locus for the effects of the neuropeptide on the expression of fear and anxiety. Intriguingly, fetoplacental 11 β -HSD inhibition also permanently increases GR and MR in the offspring amygdala. A direct relationship between brain GR levels and anxiety behaviors is supported by transgenic mice with selective loss of GR in the forebrain, which exhibit reduced fearfulness.

Intriguingly, low-birth-weight humans also exhibit HPA hyperactivity in adult life.

11 β -Hydroxysteroid Dehydrogenase Type 1 in the Brain

So what was the role of Monder's original 11 β -HSD (type 1), highly expressed in liver, adipose tissue and the brain? Studies in intact cells from liver, fat, lung, and other sites have shown that 11 β -HSD1, although bidirectional in tissue homogenates, is a predominant 11 β -ketoreductase in intact cells. This reaction regenerates active glucocorticoids from inert 11-keto forms. A similar directional predominance is seen in the intact liver *ex vivo* and in rodents and humans *in vivo*. In the brain, 11 β -HSD1-like immunoreactivity and mRNA are widespread. Fetal rat hippocampal cells in culture express 11 β -HSD1 but no 11 β -HSD2. Intact hippocampal cells show only 11 β -reductase activity. This reaction direction increases intracellular glucocorticoid levels. In searching for functions, it was noted that licorice-derived 11 β -HSD inhibitors given to rats alter hypothalamic secretagogues in pituitary portal blood *in vivo* and activate a series of regions of the CNS, including the hippocampus, a key glucocorticoid target with high GR and MR density where glucocorticoids act to suppress HPA activity and to modulate cognitive functions.

11 β -Hydroxysteroid Dehydrogenase Type 1 and the Hypothalamic-Pituitary-Adrenal Axis

11 β -HSD1 is expressed in the hippocampus, paraventricular nucleus of the hypothalamus (PVN) and pituitary, key sites of glucocorticoid negative feedback. 11 β -HSD1 knockout (11 β -HSD1^{-/-}) mice have hypertrophied adrenals and elevated basal adrenocorticotrophic hormone (ACTH) and corticosterone levels at the nadir of the rhythm. These effects are compatible with the requirement for increased glucocorticoid production from the adrenal cortex in this mouse secondary to increased metabolic clearance of corticosterone because of the lack of glucocorticoid regeneration, notably in the liver. Unexpectedly, basal plasma corticosterone levels are also elevated in 11 β -HSD1^{-/-} mice, suggesting reduced glucocorticoid feedback on the HPA axis and increased forward drive on the HPA system. Altered central drive is rather unlikely because CRH mRNA levels in the PVN are unaltered. In contrast, some findings suggest that 11 β -HSD1^{-/-} mice have attenuated negative feedback because they show less suppression of

corticosterone to exogenous cortisol 2 h prior to restraint stress. Interestingly, recent data show that obese Zucker rats have reduced 11 β -HSD1 in the hippocampus, which may explain why this strain has reduced HPA feedback sensitivity and hence has increased corticosterone levels. Altered brain 11 β -HSD1 has been reported in pregnancy, when the HPA axis becomes refractory to stressful stimulation. Interestingly, 11 β -HSD1 activity is selectively increased in the PVN in pregnancy, so locally increased 11 β -HSD1 may further amplify glucocorticoid feedback and hence attenuate HPA activity.

11 β -Hydroxysteroid Dehydrogenase Type 1 and Brain Aging

A subgroup of aged rodents and humans shows the association of cognitive decline with a chronic elevation of plasma corticosterone levels. If glucocorticoids are maintained at low levels in rats, by adrenalectomy and low-dose corticosterone replacement, age-related impairments are reduced. The hippocampus requires glucocorticoids for neuronal function and survival but is especially vulnerable to the adverse effects of chronic glucocorticoid excess, which causes atrophy of dendrites and cognitive dysfunction. Therefore, chronic glucocorticoid overexposure has been implicated in the pathogenesis of age-related decline in hippocampus-associated cognitive functions.

In primary cultures of hippocampal cells, 11 β -HSD1 potentiates kainic acid-induced neurotoxicity, not only by corticosterone but equally by intrinsically inert 11-dehydrocorticosterone, an effect prevented by carbenoxolone. 11-Dehydrocorticosterone increases kainic acid hippocampal toxicity *in vivo*, an effect also blocked by carbenoxolone. Crucially, old 11 β -HSD1^{-/-} mice learn as well as young mice in hippocampus tasks and avoid the cognitive decline seen in the majority of aged wild-type mice. This cognitive protection in aged 11 β -HSD1^{-/-} mice is associated with reduced intrahippocampal corticosterone levels, indicating the potency of intracellular metabolism by 11 β -HSDs in determining effective glucocorticoid action on target receptors. *In situ* hybridization studies in postmortem human brain material show high expression of 11 β -HSD1 mRNA in the hippocampus, prefrontal cortex, and cerebellum, mirroring rodent findings. In two small randomized double-blind placebo-controlled cross-over studies, the administration of the 11 β -HSD inhibitor carbenoxolone improved verbal fluency after 4 weeks in ten healthy elderly men and improved verbal memory after 6 weeks in 12 elderly patients with type 2 diabetes. Plasma cortisol was unaltered, suggesting that 11 β -HSD1 does not modulate HPA axis feedback

in humans, at least at the morning peak. Intriguingly, 11 β -HSD1 may play a role in pathogenesis because rare haplotypes of the HSD11B1 gene are associated with a risk of Alzheimer's disease.

Conclusion

11 β -HSDs interconvert active glucocorticoids and inert 11-keto forms. This seemingly obscure reaction is important in peripheral tissues and the CNS, determining glucocorticoid access to nuclear receptors and hence biological effects in health and disease. 11 β -HSD1 is an 11 β -ketoreductase that amplifies intracellular glucocorticoid levels. Studies in 11 β -HSD1^{-/-} mice show a role in HPA feedback. Deficiency of 11 β -HSD1 reduces intracerebral glucocorticoid levels and prevents the emergence of cognitive deficits with aging. 11 β -HSD2 is a potent 11 β -dehydrogenase, which is little expressed in the adult CNS but which plays an emerging role in preventing premature glucocorticoid actions on the developing nervous system. The maintenance of fetoplacental 11 β -HSD2 and the inhibition of 11 β -HSD1 have therapeutic potential.

Glossary

- Blood pressure (BP)** The pressure of the circulating blood on the walls of the arteries and veins. BP is usually measured with a sphygmomanometer in millimeters of mercury (mmHg).
- Coronary heart disease (CHD)** A disease associated with insufficient blood flow to the heart muscle, including myocardial infarction and angina pectoris.
- Diastolic blood pressure (DBP)** The lowest BP within a cardiac cycle.
- Hypertension** Elevated levels of arterial BP. According to Joint National Committee criteria of 2003, hypertension is systolic blood pressure levels over 140 and/or DBP levels over 90. Individuals in the prehypertensive range of 130–139 and/or 80–89 are at twice the risk of developing

	hypertension compared to those with lower values.
<i>Mental stress testing</i>	A method used to elicit cardiovascular stress reactivity in a laboratory setting through the administration of engaging, challenging, or aversive stimuli (stressors).
<i>Risk factor</i>	An attribute of individuals that is associated with an increased likelihood for developing a specific disease compared to individuals without the attribute.
<i>Systolic blood pressure (SBP)</i>	The peak blood pressure within a cardiac cycle.

Cardiovascular reactivity is defined as an individual's propensity to display cardiovascular reactions of greater or lesser magnitude compared to a baseline value when encountering stimuli or situations experienced as engaging, challenging, or aversive.

Cardiovascular Reactivity and Disease

It has been suggested that exaggerated cardiovascular reactivity plays an etiological role in cardiovascular disorders such as hypertension and CHD. Folkow suggested that the repeated elicitation of the defense reaction, which is associated with enhanced BP and heart rate (HR), translates into sustained hypertension by causing vascular hypertrophy in genetically susceptible or hyperreactive individuals. Because the normal outlet of the defense reaction (physical work) is inhibited during psychological stress, disruption of bodily homeostasis occurs. Through the repeated surges in arterial pressure and overperfusion of inactive muscles, lasting changes of the peripheral vascular resistance and a resetting of the baroreceptor set point may occur. Stress may further hamper adequate BP regulation by increasing renal vascular resistance, causing antinatriuresis with sodium retention, a decrease in the glomerular filtration rate, and the stimulation of renin release. Thus, it has been proposed that the development of high BP is stress-related.

Cardiovascular hyperreactivity has also been linked to the occurrence of CHD events. It has been hypothesized that exaggerated BP responses can cause endothelial injury, leading to accumulating atheroma, increasing the risk for cardiac arrhythmia. The adverse effects of stress are believed to be mediated by the autonomic nervous system, mainly enhanced sympathetic activity and subsequent physiological responses. For example, high plasma levels of norepinephrine and epinephrine that are associated with hyperreactivity may, in combination with cortisol, be toxic to the coronary vasculature, constituting

an additional mechanism mediating the adverse effects of stress on the cardiovascular system.

A number of cross-sectional studies show that cardiovascular hyperreactivity is more prominent among individuals at an increased risk of developing hypertension and CHD. In addition, mental stress is a potent trigger of myocardial ischemia both in the laboratory and in the ambulatory state among cardiac patients. Also, results from prospective studies show that cardiovascular reactivity may be a risk factor in cardiovascular disease progression. Although the evidence is not conclusive, studies have found that cardiovascular responses to standardized mental stress testing can predict the development of hypertension, left ventricular mass, and atherosclerosis. Excessive BP increases during exercise have also been suggested as a marker of future hypertension and to be associated with an increased risk of cardiovascular mortality.

Because growing evidence suggests that exaggerated cardiovascular responses are a risk factor or marker for the development of cardiovascular disease, research on cardiovascular stress reactivity has focused on characterizing the determinants of hyperreactivity and identifying possible ways of modifying it.

Physiological Parameters

The most commonly measured variables during mental stress reactivity testing are BP and HR. In general, noninvasive BP measurements during laboratory testing require multiple measurements made at frequent intervals (e.g., every 1–2 min). Automatic or semiautomatic devices are preferred, using a variety of available methods, such as Korotkoff sounds, oscillometry, and ultrasound.

HR recordings are usually derived from interbeat interval information available from recording the electrocardiogram (EKG) via electrodes adhered to the chest. Automated BP monitors often include measurements of HR from either EKG signals or arterial pulse detection. Holter monitoring records the EKG waveform over 24 h and involves several algorithms to describe patterns associated with the underperfusion of the heart muscle.

For continuous noninvasive BP monitoring, spectral analysis can be used, allowing the computation of short-term BP variability and baroreflex sensitivity. Newer noninvasive techniques such as impedance cardiography make it possible to document a more complete hemodynamic pattern of the stress response, including measurements of cardiac contractility, cardiac output, and vascular resistance. These measures add important new information to the area of cardiovascular reactivity research.

Assessments

Reactivity testing in the laboratory typically consists of an initial rest (baseline) period followed by a period during which the subject is exposed to a stressor. During baseline, the individual should be stimulated minimally by external events, that is, be in a relaxed state. Reactivity is quantified as a change score, calculated as the difference between resting baseline levels and mean or peak levels during stress. To increase reliability, two or more measurements should be taken and averaged for each condition. Because reactivity scores are sometimes correlated with baseline levels, residualized change scores may be calculated to eliminate baseline effects on the calculated change scores.

Stress Tasks

Stimuli (stressors) used in laboratory stress testing have different characteristics. One distinction is made between psychological stressors and physical stressors. Some widely used and well-characterized psychological stressors with emotional and/or cognitive challenging components are mental arithmetic, mirror tracing, anger interview, public speech, video games, and the Stroop test. Physical stressors commonly used are isometric handgrip, dynamic exercise, and the cold pressor test. Another distinction has been made between passive and active tasks, with the cold pressor being an example of the former and mental arithmetic an example of the latter. In addition, various stressors elicit different hemodynamic patterns, reflecting β - or α -adrenergic receptor activity. For example, cold pressor predominantly activates α receptors, whereas mental arithmetic is considered to be a β -adrenergic task.

Stability

Because there are profound individual differences in both the magnitude and the patterning of cardiovascular responses to stress, it is of importance to establish the stability of the response magnitude and patterning to a given stressor. Numerous studies suggest the BP and HR reactivity show acceptable test-retest reproducibility measured over both the short and long term. In general, the highest stability coefficients have been found for SBP and HR levels and for SBP and HR reactivity scores during standardized mental stress testing, with a somewhat lower stability for DBP levels and reactivity scores. Studies also indicate that the higher test reliability can be achieved by aggregating measurements across multiple stimuli and by aggregating over multiple tasks administered on multiple occasions. Thus, evidence suggests that

BP and HR reactivity in the laboratory constitute a stable individual trait.

Generalizability

The reactivity definition discussed so far refers to individual differences in the response magnitude to a given stimulus on a particular occasion. The underlying assumption is that hyperreactivity to laboratory stressors is a generalized individual propensity and that the individual response pattern elicited by laboratory-induced stress can be generalized to responses in the natural setting during encounters with everyday stress. Noninvasive ambulatory blood pressure (ABP) monitoring provides the opportunity to study the relationship between cardiovascular responses in the laboratory and in natural settings, and several studies have examined the relationship between cardiovascular measurements in the laboratory and during everyday life using automated ABP recordings. Most studies have found a strong positive relationship between ABP levels and laboratory BP levels, whereas the relationship between laboratory-induced BP reactivity and ambulatory levels or variability seems less consistent.

Risk Factors and Hyperreactivity

A number of cross-sectional data show that cardiovascular hyperreactivity is more prominent among individuals at an increased risk of developing hypertension and CHD. Individual differences in cardiovascular reactivity to stress are, in part, mediated genetically. Also, male gender, family history of CHD, borderline hypertension, African American ethnicity, and type A behavior and depression have all been associated with an increased risk for CHD, and these high-risk group have independently shown exaggerated cardiovascular reactivity in several studies. In addition, smoking status, serum cholesterol levels, fasting insulin levels, left ventricular hypertrophy, and carotid artery atherosclerosis are all important independent risk factors for cardiovascular disease. A number of studies have investigated the relationship between these risk factors and cardiovascular hyperreactivity.

1. Gender. Sex differences exist in resting baseline and HR levels, with women having higher HR and men, in general, having higher BP levels (until the age of 60). In general, men are more SBP reactive than women, whereas there are small or no differences in DBP reactivity. Studies on HR reactivity are inconsistent, with men and women having an equal likelihood of displaying augmented HR reactivity.

2. Hypertension. In a meta-analysis of published reactivity studies related to hypertension, it was concluded that the majority of studies have shown that individuals with a positive family history of hypertension and individuals with borderline hypertension display enhanced BP reactivity compared to individuals without a family history of hypertension and to normotensive controls.

3. Ethnicity. African Americans have enhanced cardiovascular hyperreactivity compared to Caucasians. Studies also show that African Americans display increased total peripheral resistance during mental stress testing in the laboratory compared to Caucasians.

4. Type A behavior. Individuals with type A behavior (i.e., showing enhanced hostility, time urge, and competitiveness) have increased sympathetically mediated reactivity compared to type B individuals. It has been suggested that it is the hostility component in the type A behavior pattern that is most closely related to enhanced cardiovascular reactivity.

5. Depression. Accumulating evidence show that depressive symptoms are related to cardiovascular morbidity and mortality. Studies evaluating the association between depression and hyperreactivity have so far only shown moderate support for a link between depressive symptoms and enhanced cardiovascular reactivity.

6. Smoking. Evidence is accumulating that smoking, in combination with psychological stress, may be particularly harmful, both because smoking increases in stressful situations and because the cardiovascular effects of smoking combined with those of psychological stress may be synergistic. Nicotine itself has acute effects on the activity of the cardiovascular system, leading to an increase of both BP and HR, but smoking status per se (being a smoker or a non-smoker) does not seem to affect the magnitude of the stress response. Nicotine administration has been found to enhance HR reactivity, but there is no conclusive evidence that nicotine enhances cardiovascular reactivity in general.

7. Lipids. Several studies have reported an association between serum lipid levels and cardiovascular reactivity to laboratory stressors, but findings are equivocal. Associations have been found to be lower or completely absent in youngsters but evident among older adults, which suggests an age-dependent association. Some evidence suggests that an enhanced cardiac responsiveness is associated positively with low-density lipoprotein levels but is related inversely with high-density lipoproteins.

8. Insulin resistance. Insulin resistance is part of the metabolic syndrome associated with hypertension and cardiovascular alternations. One mechanism

through which insulin may be linked to hypertension is through the stimulation of sympathetic nervous activity. Thus, insulin concentrations may be correlated with indices of sympathetic activity such as hyperreactivity even before it affects resting BP. Fasting insulin concentrations have been associated with cardiovascular reactivity to exercise. There are also studies indicating that insulin resistance may be more closely related to BP levels during mental stress testing than during rest.

9. Left ventricular mass. Left ventricular hypertrophy is an important target-organ consequence of hypertension and an independent risk factor for cardiovascular morbidity and mortality. Several studies have shown that left ventricular mass is poorly related to casual clinic BP levels, whereas some studies have shown stronger associations to daytime ambulatory BP levels and variability and to BP levels during mental stress testing. Left ventricular mass (index) has also been found to be associated with a vasoconstrictive response pattern among children and adolescents. A few studies have found cardiovascular reactivity to predict the development of left ventricular mass over time. However, further evidence is needed to establish the association between stress-induced cardiovascular reactivity and left ventricular mass.

10. Atherosclerosis. Carotic intima-media thickness is an important preclinical measure of atherosclerotic vascular disease and has been strongly associated with the development of CHD. BP responses to mental stress have been found to be associated to intima-media thickness as well as plak height. Although studies have also shown reactivity to mental stress to be prospectively related to intima-media thickness, further evidence is required to establish the relationship between cardiovascular hyperreactivity and atherosclerosis.

11. Inflammation. Atherosclerosis is considered an inflammatory disease. In the atherosclerotic process, proinflammatory cytokines, derived from excess adipose tissue, increase the expression of adhesion molecules that promote the sticking of blood leukocytes to the inner surface of the arterial wall. Recent studies report that acute psychological stress in humans significantly increases the serum concentrations of proinflammatory cytokines such as interleukin-6 (IL-6) and the IL-1 receptor antagonist (IL-1Ra), suggesting that stress reactivity may affect the atherosclerotic process by eliciting an activation of the inflammatory response system.

Conclusion

Cardiovascular hyperreactivity is associated with several risk factors for cardiovascular morbidity and

mortality, and, although the mechanisms are not fully established, there is evidence suggesting that heightened cardiovascular reactivity may independently contribute to the development of CHD and hypertension.

Stress Management and Quality of Life

Glossary

White-coat hypertension

Blood pressure that is elevated when measured in the clinic by a physician or nurse but normal when measured in other situations.

Hypertension

Sustained elevated blood pressure.

Prevalence

Hypertension is the condition of sustained elevated arterial blood pressure. The criteria for defining hypertension are somewhat arbitrary because the distribution of blood pressure level in the population is continuous. The current definition of hypertension is a systolic blood pressure ≥ 140 mmHg and diastolic pressure ≥ 90 mmHg. Most authorities regard a blood pressure in the range 130–139/85–89 mmHg as high-normal, although the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure has defined levels of 120–139/80–89 mmHg as prehypertensive. Risk of coronary heart disease and stroke is directly related to blood

pressure level, so hypertension defines those individuals who are at an especially elevated risk.

The prevalence of hypertension in the United States is approximately 29% in men and 30.5% in women. Recent figures from the United Kingdom indicate that approximately 37% of men and 34% of women are hypertensive. However, blood pressure tends to rise with age, so these overall figures disguise the substantial increase in hypertension in middle age. Thus, in the United States, the prevalence rises from 8.1% in men and 2.7% in women ages 20–34 years to 44.9% and 53.9% in those ages 55–64 years. There are also striking ethnic variations, with high rates in African Americans and in African Caribbean people in the United Kingdom.

Between one-third and one-half of hypertensives are not diagnosed and are unaware of their condition. Because hypertension is not consistently associated with symptoms, it is frequently identified only during routine screening, so it may continue for many years before detection. The number of diagnosed hypertensives who are not treated is substantial, whereas as many as 50% of patients who are prescribed antihypertensive medication do not have their blood pressure controlled adequately. The problem of hypertension is therefore considerable.

Etiological Factors

The etiology of hypertension is complicated. In a minority of cases, high blood pressure is associated with a specific pathological abnormality such as pheochromocytoma or a renovascular disorder. However, in most cases there is no single identifiable cause, and the condition is regarded as multifactorial. This condition was once known as essential hypertension because an elevated pressure was considered necessary to drive blood through partially blocked arteries. Now, cases without a single cause are sometimes called primary hypertensives to distinguish them from individuals whose hypertension is secondary to another disease. Hypertension typically develops over many years, with blood pressure gradually increasing until it reaches threatening levels. The most consistent predictors of future hypertension are a positive family history, a blood pressure in childhood or early adult life that is above average, and elevated body weight. High salt and alcohol intake also contribute.

The primary reason for considering stress to be an etiologic factor relates to the influence of the autonomic nervous system and neuroendocrine factors in hypertension. There is clear evidence of increased sympathetic nervous system activity in hypertension, as documented through raised levels of plasma norepinephrine. Microneurographic studies have shown

elevated sympathetic nervous traffic to muscle. Hypothalamic activation may be responsible for these sympathetic responses, which in turn lead to inhibition of baroreceptor reflex sensitivity, peripheral vasoconstriction, and alterations of renal blood flow. Reduced parasympathetic activity may also be associated with the etiology of hypertension, together with the impairment of opioid-mediated counter-regulatory processes. Abnormalities of adrenocortical function have been described in some cases of hypertension, and pro-inflammatory processes may contribute as well.

The hypothesis underlying much research on this topic is that the stress-induced activation of sympathetic and other pathways occurs repeatedly over months and years in susceptible individuals, leading to hemodynamic adjustments that increase hypertension risk. Evidence relevant to this hypothesis derives from several sources, including animal and human experimental studies and investigations of the impact of adverse life experiences, chronic stressors, and psychological characteristics.

Experimental Evidence

Animal Studies

Evidence that permanently elevated blood pressure can be produced with behavioral stress in animals is controversial. Although it is clear that acute hypertensive episodes can be induced, the development of sustained hypertension is more elusive. Aversive conditions such as restraint stress, unpredictable shock, and approach-avoidance conflict produce chronic hypertension in some studies but not others. Effects vary across species and are more prominent in the presence of risk factors such as a genetic predisposition and heightened salt sensitivity. Some of the most compelling evidence comes from studies carried out by Henry and co-workers on the effects of social conflict in CBA mice. Male mice raised in isolation were placed in complex colonies that encouraged conflict. There were immediate blood pressure increases that reverted to control levels after their removal from the colony. However, irreversible hypertension developed with prolonged exposure to conflict, accompanied by alterations in catecholamine synthesis and myocardial fibrosis and degeneration. Species differences are apparent in primates as well, although hypertension can be induced by prolonged shock avoidance in rhesus monkeys.

Cardiovascular Reactivity to Acute Behavioral Stress in Humans

Blood pressure increases acutely in response to a variety of behavioral stressors in humans, ranging

from problem-solving tasks and emotionally laden interviews to painful stimuli such as the cold pressor test. The increase in blood pressure is typically accompanied by tachycardia, inotropic stimulation of the heart, vasodilatation in skeletal muscle and adipose tissue, and reduced blood flow to the kidneys, skin, and viscera.

The issue of whether these responses are involved in hypertension has been the subject of much research, stimulated in the 1950s by Jan Brod. Compared with normotensives, hypertensives typically show enhanced blood pressure responses to acute behavioral stress, accompanied by greater renal vasoconstriction and increased norepinephrine turnover. However, it is possible that this exaggerated cardiovascular responsivity is the result of the complex physiological adjustments that occur in hypertension and is not primary. Attention has therefore shifted to people with normal blood pressure who are at increased risk, for example, because of genetic factors. Results have again been variable, but a meta-analysis of this literature suggests that a proportion of people with a positive family history of hypertension are more reactive to tasks involving active behavioral responses (e.g., difficult problem solving) than are those without family histories. Young people with positive family histories may also have elevated blood pressure during their everyday lives, as assessed using automated ambulatory monitoring techniques.

Longitudinal studies have also been reported, testing the hypothesis that high reactivity to behavioral stress predicts future rises in blood pressure over 5–10 years. Most trials have found evidence in favor of this hypothesis. Impaired poststress recovery in blood pressure has also been shown to predict future increases. But such effects are not always observed, probably for two reasons. First, the investigation of acute responses to behavioral stress is complex and requires the careful standardization of procedures. Different types of stimuli elicit different patterns of physiological response. For instance, some tasks such as mental arithmetic elicit blood pressure responses that are primarily sustained through increased myocardial contractility and cardiac output, whereas others predominantly elicit increases in peripheral vascular resistance. These response profiles may not all be equally relevant to hypertension. Second, the nature of the hypothesized relationship between stress responsivity and hypertension should be considered. [Figure 1](#) outlines the presumed sequence of events. Heightened cardiovascular responses to acute stress *per se* will not increase the risk of hypertension. Such responses are relevant only if they are representative of the individual's experience during daily life. Stress-related factors are most likely to contribute to hypertension if reactive individuals are exposed over months or years to environments that elicit damaging patterns of intense response. This interaction has only

Figure 1 Schematic outline of the way in which acute cardiovascular and neuroendocrine stress responsivity might contribute to hypertension risk. Highlighted boxes indicate the highest risk group. The combination of high risk status, high stress responsiveness, and prolonged exposure to situations that provoke appropriate physiological responses is necessary.

been evaluated in a few studies to date. It should also be kept in mind that stress is only one of many factors contributing to hypertension and does not affect all those at risk in the same fashion.

Psychological Characteristics

The many comparisons that have been made between hypertensive patients and controls in terms of personality typically suffer from two limitations. First, the diagnostic label of hypertension may cause psychological distress and lead to changes on psychological tests. Second, because much hypertension is not diagnosed, any differences observed may be restricted to those who seek medical attention. Population-based studies involving measurements of blood pressure and psychological factors are therefore required.

Some population studies have shown prospective associations between tension or anxiety and future hypertension, but effects are small and inconsistent. A more persuasive body of evidence has linked hypertension with the ways that people cope with angry and hostile feelings. This notion was stimulated in the mid-1970s by research on hypertension and urban stress in Detroit. It was found that hypertension was more prevalent and that blood pressure was generally higher among black men living in high-stress areas (defined by population density, crime rate, and family instability) who also inhibited anger expression. Subsequent research has supported the link between anger inhibition and high blood pressure in a number of populations. However, it has also been found that the expression of anger is related to blood pressure, so perhaps the appropriateness of anger display and hostility management is more critical.

Hypertension is associated with mild deficits of cognitive function, as assessed by measures of memory, attention, and abstract reasoning. These effects vary with age, education, and whether blood pressure is being treated. The extent to which these impairments affect the performance of daily activities is not known. They may be the result of central nervous system neurophysiological sequelae of high blood pressure.

Lifestyle and Adverse Life Experience

What types of real-life stressful experience are likely to be associated with hypertension? If the inferences from laboratory studies are correct, they are experiences that are repeated or sustained over years and elicit active efforts to cope and maintain control. Acute traumatic events would not be expected to stimulate appropriate long-term cardiovascular and neuroendocrine responses, and indeed there is little

evidence that acute life events are associated with the development of hypertension. In contrast, some forms of chronic stress are associated with sustained increases in blood pressure. Experiences such as caring for demented relatives, marital conflict, and the experience of racism in ethnic minorities have been related to increased blood pressure. Interesting results have emerged from studies of migrants from traditional, isolated, rural cultures to modernized, developing and developed societies. For example, increases in blood pressure have been recorded among young adults from the Luo tribe in western Kenya who migrated to Nairobi. The blood pressure rise was associated with a higher salt intake and greater body weight, but stress-related increases in the sympathetic nervous stimulation may also have been involved. Similarly, studies of migrants from the isolated Pacific Tokelau islands to New Zealand have shown that blood pressure increases are greater among those who establish extensive contact with non-Tokelauans compared with individuals who maintain traditional ethnic affiliations.

Blood pressure has been shown in several studies to be associated inversely with the size of social networks and the extent of social support. A striking illustration of the protective effects of a tranquil lifestyle and supportive environment is illustrated in [Figure 2](#). This shows results from a long-term study of Italian nuns in a secluded order compared with nonsmoking, age-matched women living in local communities. It can be seen that the typical age-related increases in blood pressure were attenuated among the nuns, which was coupled with a significantly lower incidence of fatal and nonfatal cardiac events.

Work and Hypertension

Some types of work might be expected to have the characteristics that would lead to acute stress-induced increases in blood pressure and sympathetic activation, thereby heightening the risk of hypertension. An important early study by Cobb and Rose of air traffic controllers demonstrated an increased incidence and earlier onset of hypertension among men working in this highly demanding occupation compared with controls. Subsequently, an automated ambulatory recording apparatus has been used to measure blood pressure repeatedly as people go about their everyday lives. Blood pressure is typically higher at work than at home, and it is elevated in people who work in high-demand, low-control jobs. For instance, in the Work Site Blood Pressure Study in New York City, job strain (high demand, low control) was an independent predictor of hypertension after controlling for age, body mass index, type A behavior, 24-h sodium

Figure 2 Results from a 30-year longitudinal study of 144 nuns from a secluded Catholic order and 138 age-matched nonsmoking women from the local community. The absence of age-related increases in blood pressure in the nuns is clear. Reproduced with permission from Timio et al. (1997). excretion, physical activity at work, education, smoking, and alcohol consumption. Longitudinally, individuals exposed to more years of high job strain had higher blood pressure. This is consistent with the evidence that lack of control over challenging situations is associated with heightened physiological activation.

White-Coat Hypertension

White-coat hypertension is the phenomenon of transiently raised blood pressure during measurement in the clinic by a physician or nurse compared with blood pressure as recorded at home or using an ambulatory recording apparatus. The definition of white-coat hypertension is somewhat arbitrary, but one study found that 20% of patients referred with a diagnosis of hypertension, whose diastolic pressure remained in the range of 90–104 mmHg on several occasions in the clinic, were normotensive during ambulatory monitoring. The phenomenon is clearly stress-related, in that it is dependent on physiological responses to the threatening clinical situation. People who exhibit white-coat effects do not have unusual psychological profiles, but do show heightened blood pressure responses to stressful behavioral tasks. There is also limited evidence that white-coat hypertension is associated with the secondary effects of hypertension such as left ventricular hypertrophy. However,

the boundaries and the significance of the problem remain poorly understood.

Stress Management and Quality of Life

Despite research over the past quarter of a century, the use of stress management in hypertension remains controversial. A number of well-controlled trials have shown that stress management involving relaxation training (sometimes accompanied by biofeedback) can reduce the blood pressure and medication needs of hypertensives. Problems have arisen, however, in establishing genuine pretreatment levels of blood pressure against which to measure the effects of stress management. Blood pressure may fall progressively with repeated measurement due to adaptation and the habituation of white-coat effects, and these phenomena may be confused with the effects of stress management. The evidence for specific techniques such as transcendental meditation reducing the blood pressure of hypertensives is inconclusive.

The pharmacological treatment of hypertension is a complex and continuously developing field. Older treatments, such as β -adrenergic blockade and diuretics, have been joined by calcium antagonists and angiotensin-converting enzyme inhibitors. Some hypertensive medications have side effects that lead to impairments in the health-related quality of life. Stress

management may play a role in particular types of cases. One is the individual whose blood pressure is only mildly elevated (e.g., 170/100 mmHg), who might be able to reduce blood pressure without recourse to lifetime medication. The second is the established hypertensive who is already medicated but who wishes to try alternative methods to reduce drug intake or because their blood pressure is poorly controlled. Other behavior changes also benefit hypertensives, including weight loss, increased physical exercise, and restriction of salt and alcohol intake. Stress management should therefore be applied in the context of these other aspects of behavior modification.

Glossary

Adaptation A change that reduces the physiological strain produced by stressful components

Conductive heat transfer

Convective heat transfer

Evaporative heat transfer

Metabolic heat production

of the total environment. This change may occur within the lifetime of an organism (phenotypic) or be the result of genetic selection in a species (genotypic). The net rate of heat transfer by conduction down a thermal gradient, within an organism or between an organism and its external environment.

The net rate of heat transfer by convection between an organism and its external environment or the transfer of heat with the bloodstream from the thermal core through the thermal shell to the heat-dissipating body surface.

The loss of heat energy from the body to the ambience by evaporation of water from the skin and the surface of the respiratory tract.

The rate of transformation of chemical energy into heat in an organism.

<i>Radiant heat exchange</i>	The net rate of heat exchange by radiation between an organism and its environment.
<i>Temperature regulation</i>	Maintenance of the temperature of a body within a restricted range under conditions involving variable internal or external heat loads.
<i>Thermal stress</i>	Any change in the thermal relation between a temperature regulator and its environment that, if uncompensated by temperature regulation, would result in hyper- or hypothermia.
<i>Thermo-effector</i>	An organ and its function that affect heat balance in a controlled manner as part of the process of temperature regulation.

Thermal Balance and Body Temperature

If body temperature is to be maintained at a constant level, there has to be a thermal equilibrium. This means that heat production or heat gain and heat loss must be equal. Under resting conditions, basal metabolic heat production, which occurs due to muscle contractions, to biosynthesis of molecules within the body, and to the activity of ion pumps, is predominantly counteracted by so-called dry heat loss. Dry heat loss consists of radiation, convection, and conduction of heat from the body to the surroundings and is dependent on and proportional to the temperature difference between body and surroundings. This means that a dry heat loss would be equal to zero at an ambient temperature of 37°C for a human subject; at lower temperatures it would increase and at higher temperatures the body would even gain dry heat from the surroundings. However, dry heat loss from the body also depends on the conduction and convection of heat within the body and thus on peripheral blood flow. Vasoconstriction of skin vessels prevents heat flow from the body core to the surface, and the activation and recruitment of additional (to the basal) heat production can be delayed to a lower ambient temperature. As a consequence, there is a so-called thermoneutral zone, a range of ambient temperatures in which heat loss can be matched to resting heat production by vasomotor adjustments. For humans, the range of the thermoneutral zone is between ambient temperatures of 28 and 32°C in nonmoving air. Beyond the lower limit of the thermoneutral zone, body temperature can be kept constant only if regulatory mechanisms increase thermogenesis in proportion to heat loss. In humans, heat production, predominantly due to the activation of shivering, can be increased as much as three to five times the basal metabolic rate. At an ambient temperature, which requires more than the maximum of

available heat production to keep the body core temperature constant, the lower limit of the thermoregulatory range is reached. When this limit is passed, hypothermia develops, which results in cold death. Beyond the upper limit of the thermoneutral zone, thermal balance is achieved by an additional heat loss mechanism, the evaporation of sweat (wet heat loss in contrast to the dry heat loss mentioned earlier). To a small degree of about 20% of the total heat loss, evaporative heat transfer also contributes to the heat loss under thermoneutral conditions. This is achieved by evaporation of water that has diffused either to the skin or from membranes of the respiratory tract; this is called insensible perspiration. Evaporation of water from the skin depends on the difference of vapor pressure between skin and surrounding air. This means that evaporative heat loss is difficult under conditions of high relative humidity. At an ambient temperature higher than 37°C and saturated vapor pressure of the surrounding air (e.g., the situation after a tropical rain on a very hot day), evaporative heat loss can become impossible.

At the upper limit of the thermoneutral zone, additional (to the insensitive) evaporative heat loss is achieved by activation of glandular water loss via sweat glands. When the ambient temperature exceeds that of the body, evaporation of sweat remains the only mechanism of the body to keep the temperature constant. The high effectiveness of thermoregulatory sweat secretion is based on the high amount of heat that is lost by evaporated water (2400 kJ/l). In humans, sweating rates of more than 2 l of water per hour can be observed under thermal stress. This means that an amount of heat can be dissipated by the evaporation of sweat that corresponds to seven times the basic metabolic heat production. At an ambient temperature that requires more than the maximum of available heat dissipation to keep the body temperature constant, the upper limit of the thermoregulatory range is reached. When this limit is passed, hyperthermia develops, which can result in heat death. A schematic diagram illustrating thermal balance within and beyond the zone of normothermy is shown in [Figure 1](#).

Hyperthermia develops at ambient temperatures higher than the upper limit of the thermoregulatory range (see [Figure 1](#)). Also, during exercise, the rate of heat production increases above its level at rest mainly due to skeletal muscle contractions. The exercise-induced increase in heat production occurs immediately at the onset of exercise so that the rate of heat production exceeds the rate of heat dissipation. Therefore, body temperature is already rising during the early stage of exercise. When core temperature rises, heat-dissipating mechanisms (predominantly evaporation of

Figure 1 Schematic diagram illustrating thermal balance. Within the range of ambient temperatures between T_1 and T_4 there is an equilibrium between heat production and heat loss. Below T_1 , more heat is lost than can be produced (hypothermia develops). Above T_4 , production and influx of heat exceed the capacity for evaporative heat loss (hyperthermia develops). Between T_2 and T_3 (thermoneutral zone), heat loss can be matched to resting heat production by vasomotor adjustments. At T_2 there is a maximum of peripheral vasoconstriction, whereas at T_3 there is a maximum of peripheral vasodilation. MR, metabolic rate; TNZ, thermoneutral zone. Modified from Brück (1983), with permission from Springer-Verlag.

sweat) are activated, and the core temperature rises further with a smaller slope. Especially under conditions of high ambient temperature and/or high relative humidity, exercise can cause severe hyperthermia. During prolonged, exhausting exercise such as marathon running, rectal temperatures of higher than 41°C have been measured.

Physiological Responses to Heat Stress

During exposure to external heat or during production of additional internal heat, a number of vital homeostatic functions are influenced or even impaired. Important changes in cardiovascular responses, body fluid balance, endocrine responses, and responses of the immune system are described. In part, these adjustments serve to prevent or limit a developing hyperthermia.

Cardiovascular Responses

When the body has to counteract an increased heat load, it must direct enhanced blood flow to the skin, first to transport heat from the body core to the surface for dry heat loss (radiation, convection, conduction) and, second, to supply the water and electrolytes that are necessary for sweat formation.

Cardiovascular adjustments to whole body heating in humans can be summarized as follows. During an aggressive heating of the whole body surface with water-perfused suits, the skin temperature rises from 35 to 40.5°C and the blood temperature increases from 36.7 to 39.1°C . These body temperature changes are accompanied by a continuous rise of cardiac output from 6.4 to 13 l/min. The doubling of cardiac output is, to a large degree, driven by an increased heart rate (rise of about 30 beats per minute per degree increase of core temperature), whereas stroke volume changes little. Increased cardiac output during heat stress is accompanied by a regional redistribution of blood. Despite the doubled cardiac output, splanchnic, renal, and muscle blood flows are reduced by 1.2 l/min during the heating period. Thus, skin blood flow can approach about 8 l/min during external heat stress (6.6 l/min additional cardiac output plus 1.2 l/min redistributed blood). The dramatic increase in skin blood flow during heat stress occurs over the entire body surface and is distributed between two general vessel types: capillaries and arteriovenous anastomoses (AVAs). AVAs are shunt vessels between arterioles and venules. Opening AVAs accelerates blood flow and thereby heat flux substantially. AVAs are concentrated on the so-called acral sites of the skin (tips of extremities, nose, ears, tongue, and lips); there

is a lack of AVAs in nonacral sites (torso, forearms, upper arms, and legs). The major mechanisms by which skin blood flow is increased during heat stress are (1) a reduced activity in sympathetic vasoconstrictor nerves, (2) an increased activity of a sympathetic active vasodilator system, and (3) direct local vasodilative effects of elevated skin temperature. Cardiac output and distribution/redistribution of blood under resting conditions and during heat stress are summarized in [Figure 2](#).

It has to be noted that the increase of thermoregulatory skin blood flow is limited by the demands of the working muscles during hyperthermia induced by physical exercise.

Effects on Body Fluid Balance

Maintenance of body fluid volume and composition is strongly impaired by heat stress. Exposure to heat species specifically results in sweating, panting, or saliva spreading to increase evaporative heat transfer to the environment. As a consequence, the constancy of total body water is disturbed by its considerable decrease. In humans sweating heavily, water loss from the body can exceed 2 l/h. All body fluid compartments and intracellular fluid, as well as extravascular and intravascular extracellular fluid, contribute

Figure 2 Distribution of human cardiac output between the skin and other major organs. The left column illustrates the conditions at rest in normothermia and the right column shows the conditions during severe hyperthermia when core temperature is higher than 39°C. From Rowell (1983), with permission from the American Physiological Society.

to the water loss in heat stress. Without fluid replacement, a thermal dehydration results in hypovolemia (reduced intravascular compartment size) and hyperosmolality (increased plasma osmolality). Hypovolemia and hyperosmolality have adverse effects on thermoregulatory responses to heat stress. The rate of evaporative water loss is reduced in dehydrated humans and animals. As a consequence, heat stress results in faster onset and a stronger increase of body temperature in dehydrated subjects. Under conditions of restricted fluid supply, conservation of water is essential for survival. Therefore, the dehydrated organism tolerates an elevation of body temperature under conditions of heat stress to avoid a further loss of water by evaporation. This phenomenon is demonstrated impressively in the camel living at an ambient temperature of 34°C in the morning and 41°C in the afternoon. In the fully hydrated camel, which is watered every day, body temperature varies by about 2°C, between 36 and 38°C. When the camel is deprived of drinking water, however, daily body temperature fluctuations may increase to as much as 7°C, between 34 and 41°C. For a dehydrated camel, the amount of heat that is stored by this mechanism during the day equals a saving of 5 l of water. These interactions between water balance and body temperature control under the conditions of high external heat load are shown in [Figure 3](#).

Corresponding observations are made under conditions of high internal heat load (exercise). At ambient temperatures higher than 30°C, an exercising man who is dehydrated responds with a strong increase of core temperature, while water replacement allows

Figure 3 Daily body temperature fluctuations in a well-watered camel (about 2°C, bottom) and in a dehydrated camel deprived of drinking water (about 7°C, top). Modified from Schmidt-Nielsen et al. (1957), with permission from The American Physiological Society.

sustained sweating under the same external conditions so that the core temperature is maintained at a constant level. Sweating is thus inhibited by dehydration. In other words, the development of hyperthermia due to external or internal heat stress is accelerated if there is a strong demand for water conservation to avoid a pronounced deviation in the body fluid balance. Hypovolemia and hyperosmolality inhibit evaporative water loss in many species. It thus seems to be an evolutionary strategy to try to maintain body fluid balance during thermal dehydration with the consequence of a temporally developing hyperthermia.

Endocrinological Responses

Circulating levels of numerous hormones or amounts of hormones excreted with the urine change significantly under conditions of heat stress. As pointed out earlier, there are close interactions between heat defense strategies and the conservation of body fluid in hyperthermic conditions. Even a moderate level of dehydration by heat exposure or exercise affects the circulating levels of hormones that are involved in fluid and electrolyte homeostasis. Increasing dehydration is correlated with increments in arginine vasopressin, plasma renin activity, and aldosterone, hormones involved in the retention of water and electrolytes. In contrast, the secretion of atrial natriuretic peptide, which stimulates the excretion of sodium, is decreased by dehydration. Circulating levels of prolactin and adrenocorticotrophic hormone, which both belong to the so-called stress hormones, are elevated during heat stress. Apparently, whenever thermal stress (heat or cold) induces marked discomfort or physiological strain, the hypothalamic-pituitary-adrenal axis is activated significantly.

Acute heat stress reduces serum thyroid-stimulating hormone. Further, decreased thyroid activity during chronic exposure to heat is indicated by attenuated circulating levels of thyroxine (T_4) and triiodothyronine (T_3). Finally, activity of the sympathoadrenomedullary system is also altered under hyperthermic conditions. The effects of acute and chronic heat exposure have to be differentiated. In most reports dealing with this question, an acute exposure to heat results in a rise of circulating epinephrine (E), whereas increases, no changes, or even decreases of norepinephrine (NE) can be observed depending on the experimental conditions, especially the intensity of the imposed heat stress. Long-term acclimation to heat is accompanied more constantly by a reduced excretion of NE, as long as the acclimation temperature is not excessively high. In summary, if the physiological strain evoked by acute heat stress is sufficient, an elevation of circulating or excreted A and NE is observed. Long-term exposure to heat may be accompanied by an attenuation of sympathetic activity. The most important endocrinological responses to heat stress are summarized in [Table 1](#).

Immunological Responses

The thermal effects of fever, an evolutionarily conserved component of the acute phase response, has been associated with better survival and a shorter duration of disease in cases of infection. A possible explanation for this classical observation derived from a number of studies in which a whole body hyperthermia was induced in humans or experimental animals and various components of the innate and the specific immune defense mechanisms were analyzed under hyperthermic conditions. The benefits of heat for the immune system include enhanced neutrophil

Table 1 Endocrinological responses to heat stress^a

<i>Hormone</i>	<i>Stimulus</i>	<i>Direction of change</i>	<i>Species</i>
AVP ACTH PRA ANG II ALD	Acute heat exposure or severe heat stress in a sauna bath or exercise	Increase in plasma	Human
AVP	Acute heat exposure	Increase in plasma	Rat
TSH	Acute heat exposure	Decrease in serum	Rat
T_3 T_4	Long-term heat acclimation	Decrease in plasma	Rat, chicken, guinea pig
E	Acute heat exposure or exercise	Increase in plasma	Human, dog, rat
NE	Long-term heat acclimation	Decrease in plasma or urine	Human, guinea pig

^aData compiled from Zeisberger and Roth (1988) and Fregly and Blatteis (1996). AVP, arginine vasopressin; ACTH, adrenocorticotrophic hormone; PRA, plasma renin activity; ANG II, angiotensin II; ALD, aldosterone; TSH, thyroid-stimulating hormone; T_3 , triiodothyronine; T_4 , thyroxine; E, epinephrine; NE, norepinephrine.

and monocyte motility and emigration, enhanced phagocytosis, increased production and activity of interferon, increased T helper cell activation and antibody production, and induction of cytoprotective heat shock proteins in host cells. These effects of hyperthermia are thought to improve the pathogen-eliminating capacity by hindering the spread of local infection. The ability to warn the immune system distant from the site of primary infection suggests that hyperthermia or infectious fever has a messenger role for the immune system.

Brain Function in Hyperthermia

The Heat Stroke Syndrome

During prolonged hyperthermia, with a body temperature of 41°C or even higher, the brain suffers severe damage, which leads frequently to death. Alterations in microvascular permeability cause the development of cerebral edema. Postmortem findings further show microhemorrhages, tissue softening, and destruction of neurons. The victim exhibits disorientation, delirium, and convulsions. This syndrome is referred to popularly as heat stroke. Heat stroke can develop in response to severe external heat exposure. The heat illness syndrome can also be caused by exercise or work in hot environments. Perhaps the most famous example of heat stroke is the traditional 7-day pilgrimage to Mecca (Saudi Arabia), the so-called Makka Hajj. During the Hajj pilgrimage of 1982, high ambient temperatures (35–50°C), in addition to the large radiant heat load of the thermal environment resulting from the presence of a large number of human bodies in a very restricted area, caused more than 1500 cases of heat stroke. About 1100 people were treated successfully, whereas several hundred died. The use of molecular techniques has provided the basis for a number of pathophysiological changes in the heat-stressed brain.

Molecular Changes in the Heat-Stressed Brain

The expression of a number of molecules is upregulated in the brain under conditions of hyperthermia. Representative examples of these molecular changes are introduced briefly in the following sections. The role of these molecules in the hyperthermic brain, especially in the manifestation of detrimental effects, is the subject of current investigation. Knowledge about mechanisms by which all these molecules, which are induced in the hyperthermic brain, contribute to the heat stroke syndrome is still incomplete. Research is focusing on the roles of these molecules in the disturbance of microvascular permeability,

formation of edema, and cell injury within the hyperthermic brain.

Heat shock proteins Exposure of cells and tissues to stressful stimuli results in a rapid induction and synthesis of a specific set of proteins. These proteins are called heat shock proteins (HSPs) because their induction was originally discovered under hyperthermic conditions. However, because these proteins are also synthesized under the influence of nonthermal noxious stimuli, they are also called stress proteins. In the hyperthermic brain, the induction of HSPs is closely related to damaged brain areas and can thus be used as markers of cell injury. However, after induction of HSPs by a moderate hyperthermia, the brain becomes more resistant to a subsequent severe hyperthermia. HSPs may therefore have some neuroprotective properties. Experimental studies demonstrated that there is a correlation between the induction of HSPs and the breakdown of the blood–brain barrier in hyperthermia.

Glial fibrillary acidic protein Hyperthermic brain injury is accompanied by an activation of glial cells as indicated by the expression of the glia cell marker protein glial fibrillary acidic protein (GFAP). Under normal conditions, this protein is predominantly expressed in astrocytes. Under pathophysiological conditions, such as heat stress, increased induction of this protein is associated with a breakdown of the blood–brain barrier and vasogenic edema. The increased synthesis of GFAP is a part of the reactive response to almost any type of central nervous system (CNS) injury. Following injury, glia cells are activated to accomplish metabolic and structural roles in the CNS.

Cytokines Activation of the immune system during infection or inflammation is characterized by the expression of cytokines in the brain. Interleukin-1 (IL-1) is regarded as the most important cytokine to cause modifications of brain-controlled functions during infection. Evidence shows that the increased expression of IL-1 within the CNS is associated with brain injury. Heat stroke-induced cerebral ischemia and neuronal damage are accompanied by an increased production of IL-1 in the damaged brain. Because the survival time of rats after experimentally induced heat stroke can be prolonged by treatment with an IL-1 receptor antagonist, a role of IL-1 (and possibly other cytokines) in the manifestation of the heat stroke syndrome is indicated.

Prostaglandins A role of prostaglandins in fever is well established. Inhibition of cyclooxygenases, the

enzymes responsible for prostaglandin formation, suppresses fever. Also, the hyperthermic response to heat stress is reduced slightly by treatment with cyclooxygenase inhibitors. In addition, the hyperthermia-induced formation of edema and cellular damage in the brain are reduced by inhibitors of prostaglandin synthesis. Thus, prostaglandins seem to contribute to the detrimental effects that are induced by hyperthermia in the brain.

Nitric oxide and carbon monoxide Nitric oxide (NO) and carbon monoxide (CO) are novel chemical messenger molecules that are involved in physiological and pathophysiological processes within the brain. NO and CO are produced by specific enzymes: NO synthases and heme oxygenases. Both of these enzymes are upregulated in the brain under conditions of heat stress. In the brain, the products of these enzymes seem to contribute to the disturbance of microvascular permeability in hyperthermia.

Adaptation to Heat

Adaptation has been defined as a set of modifications within organisms that take place during prolonged or repeated actions of an environmental stimulus, a so-called stressor. The process of adaptation improves the ability to cope with stressor-induced disturbances that interfere with the homeostasis of an organism. Such disturbances (i.e., repeated or continuous exposure to heat) evoke specific and nonspecific responses and can finally lead to functional and morphological modifications that counteract the disturbance. As a nonspecific response to various stressors, including heat, central nervous circuits are activated that lead to the stimulation of the sympathoadrenal system and the hypothalamic-pituitary-adrenal axis. This nonspecific response or emergency reaction usually decreases in its intensity in response to repeated or prolonged actions of the same stressor. Specific adaptive responses to the stressor heat may lead to changes in the capacity of the effector systems that are predominantly activated in hyperthermia and to modifications of the regulatory characteristics of the control system being responsible for the thermal homeostasis under conditions of heat stress. The most profound heat-adaptive response of the thermoeffector system in humans is the increase of the sweat rate capacity, which nearly doubles during heat acclimation. This kind of adaptation to heat develops in response to repeated exposures to heat and to repeated severe exercise. Using this mechanism, a heat stress of the same intensity leads to much smaller hyperthermia at the end of the process of heat adaptation. The second component of the stressor-specific adaptive response

to heat concerns the modifications of the regulatory characteristics. Usually, sweating is activated when the mean body temperature rises to a certain value, the so-called threshold temperature for the onset of sweating. This sweating threshold is shifted to a lower mean body temperature after repeated exposures to external heat or to repeated exercise, which includes heat load such as marathon running. This means that the heat-adapted subject starts to sweat earlier and thereby delays or even prevents the developing hyperthermia. A different type of heat adaptation is observed in residents of areas with tropical climate. Here, the onset of sweating occurs at a higher body temperature than in controls. This kind of heat adaptation can be called tolerance adaptation, meaning that the subject tolerates an increase of body temperature before sweating is activated. This observation corresponds to the physiological response of the dehydrated camel (see [Figure 3](#)) and may be regarded as an avoidance of sweating (i.e., a loss of water) when living continuously in a hot climate.

Malignant Hyperthermia

Malignant hyperthermia is caused by a rare, genetically fixed defect in the transport of calcium within the sarcoplasmic reticulum. This defect has been identified as a mutation of the ryanodine receptor (calcium release channel) in the membrane of the sarcoplasmic reticulum. Some inhalation anesthetics such as halothane or isoflurane cause excessive release of calcium from the sarcoplasmic reticulum in genetically susceptible subjects. Also, the muscle relaxant succinylcholine can act as a triggering agent for malignant hyperthermia. As a consequence, uncoordinated muscle contractions with a tremendous rise in oxygen consumption and metabolic rate induce a severe hyperthermia that is accompanied by acidosis, tachycardia, or cardiac arrhythmias. After its initiation by one of the triggering substances, malignant hyperthermia leads frequently to death.

Hypothalamic-pituitary-thyroid (HPT) axis

T4 and T3

Regulatory feedback loop between the brain (hypothalamus and pituitary gland) and the thyroid gland.

Circulating thyroid hormones (thyroxine and triiodothyronine, respectively) that have widespread effects throughout the body.

Causes of Hyperthyroidism

Behavioral and Neuropsychiatric Aspects of Hyperthyroidism

Association between Psychological Stress and Hyperthyroidism

Proposed Mechanism of Action Linking Stress and Hyperthyroidism

Glossary

Graves' disease A type of hyperthyroidism thought to be an autoimmune disease.

Hyperthyroidism Excessive functional activity of the thyroid gland leading to increased metabolism and symptoms such as weight loss, fatigue, anxiety, tremor, and increased heart rate.

Causes of Hyperthyroidism

There are multiple causes of hyperthyroidism, all leading to a state of hypermetabolic activity. As a final common pathway, all have an increase in circulating thyroid hormones (free thyroxine [T4] and free triiodothyronine [T3]), which in turn lead to a variety of symptoms: increased heart rate, weight loss, tremulousness, fatigue, anxiety, weakness, and increased tolerance to cold. The most commonly occurring type of hyperthyroidism is Graves' disease, first described in the 1830s and now known to be an autoimmune disorder. Other causes of hyperthyroidism include toxic nodular goiter, thyroid adenomas, and several types of thyroiditis (inflammatory conditions).

Each may have a different clinical presentation, but they share many of the same symptoms as well. Diagnosis is made by clinical history, laboratory determinations, and imaging studies of the thyroid gland.

Behavioral and Neuropsychiatric Aspects of Hyperthyroidism

Behavioral and psychological symptoms may be the presenting and most prominent aspects of hyperthyroidism. Patients complain of being anxious, restless, agitated, irritable, dysphoric, emotionally labile, and angry; having poor concentration and at times trouble thinking; feeling weak and fatigued; and having insomnia. More serious, and more rarely, paranoid thinking or frank psychosis can occur. The most common group of psychiatric disorders, in which the presenting symptoms may be similar, are the anxiety disorders, specifically, generalized anxiety disorder and panic disorder. Less often, there may be some symptoms overlapping with depression, but the full depressive syndrome usually is not present in the hyperthyroid individual. Even more rarely, manic symptoms may occur. Because of these symptoms, it is not uncommon for patients with Graves' disease to be prescribed psychotropic medication prior to recognition and work-up of their thyroid illness.

Association between Psychological Stress and Hyperthyroidism

The association of stress with hyperthyroidism dates back to the original case reports of the early 1800s. In 1825, Parry described the onset of a hyperthyroid state in a young woman who became symptomatic after falling down the stairs in a wheelchair. In 1835, Graves described the disease, which now bears his name, and implied that there was an innate mental disposition to the disorder. Since then, the association between stress and hyperthyroidism has been recognized, although the universality of this finding has been questioned. The majority of studies (but not all) have shown that stressful events, both negative and positive, in the year prior to the onset of the illness are more commonly seen in patients with Graves' disease than in patients with other forms of thyroid disease and in control subjects without thyroid illness. There also have been reports of an increased prevalence of Graves' disease in people under severe stress, such as refugees from German concentration camps and from the civil war in the former Yugoslavia, where there was a fivefold increase in disease incidence.

Proposed Mechanism of Action Linking Stress and Hyperthyroidism

The mechanism by which stress may lead to hyperthyroidism or, more specifically, to Graves' disease is not clear. Because Graves' disease is an autoimmune disorder, hypotheses have been made regarding the link between stress and the immune system. It has been shown that stress can affect a number of neurohormones that modulate the immune response, specifically decreasing the efficacy of this response. Stress affects the function of the hypothalamic-pituitary-thyroid (HPT) axis by suppressing the secretion of pituitary thyroid-stimulating hormone (TSH) and blunting its response to thyrotropin-releasing hormone. Furthermore, the HPT axis has feedback loops with the hypothalamic-pituitary-adrenocortical (HPA) axis, which also is very involved in response to stress. It is possible that individuals with a genetic predisposition to thyroid disease could, if their immune responsiveness is compromised, develop Graves' disease. Stress, and its effects upon immune function, could be one of the intervening variables involved in the cascade of events leading to this disorder. This theory has not been proven with any certainty, but remains a testable hypothesis.

The Hyperventilation Syndrome

Establishing the Diagnosis of Hyperventilation

Hyperventilation and Its Relation to Anxiety and Panic

Chronic Hyperventilation

Hyperventilation, Panic, and Asthma

Management of Hyperventilation

Breathing Exercises and Asthma

Glossary

<i>Alveolar PCO₂</i> (PACO ₂)	The partial pressure of carbon dioxide in alveolar space.
<i>Arterial PCO₂</i> (PaCO ₂)	The partial pressure of carbon dioxide in arterial blood.
<i>Dysfunctional breathing</i>	An abnormal pattern of breathing causing breathlessness, chest tightness, and other nonrespiratory symptoms that may not be associated with hyperventilation but that may respond to breathing retraining.
<i>End-tidal PCO₂</i> (PetCO ₂)	An uninvase measure of CO ₂ that is very close to arterial CO ₂ .
<i>Hyperventilation provocation test</i> (HVPT)	The patient is asked to hyperventilate for up to 3 min in an attempt to reproduce symptoms.

Hypocapnia

The reduction of CO₂ in the body that is the result of hyperventilation.

Respiratory alkalosis

A drop in PCO₂ with an arterial pH above 7.40 caused by hyperventilation.

Tetany

An abnormal increase in the excitability of nerves and muscles resulting in muscular spasms.

Physiology

Hyperventilation (HV) is a physiological term implying breathing in excess of metabolic requirements, thus producing arterial hypocapnia. The approach to HV requires a clear understanding of the physiological background of respiratory control. If carbon dioxide production remains constant and ventilation increases, there is an increased washout of carbon dioxide (i.e., hypocapnia) from the alveolar space with a consequent fall of alveolar PCO₂ (PACO₂) and arterial PCO₂ (PaCO₂). Stated another way, PaCO₂ below the normal range is invariably associated with a raised alveolar ventilation and excessive respiratory drive (see **Figure 1**). HV cannot be present without hypocapnia. Increases in ventilation without hypocapnia, respiratory tics, and other disorders of respiratory pattern are not HV. Following 15–20 min of voluntary hyperventilation to below 20 mmHg, hypocapnia can be maintained with only an occasional large breath, but even chronic persistent HV is associated with at least a 10% increase in ventilation. The cause or causes of this increased drive to breathe must always be sought in any individual with a HV-related disorder.

Hypocapnia and respiratory alkalosis develop rapidly after the onset of HV. If hypocapnia is sustained, renal compensation occurs through increased renal excretion of bicarbonate, but this is probably unimportant in humans. Tetany is often thought to be due

Figure 1 Relation between minute ventilation and PetCO_2 during resting breathing in eight normal subjects (closed symbols) and 16 patients with chronic hyperventilation (open symbols; two runs per subject). Each symbol is the mean of 40–100 breaths. From Gardner, W. N. (1996), *The pathophysiology of hyperventilation disorders*, *Chest* **109**, 516–534.

to a fall in serum calcium, but this has never been confirmed. There is, however, a rapid and consistent fall in the serum phosphorus level, and this provides a more likely explanation for the increase in neuronal excitability. Hypocapnic alkalosis is associated with a reduction in cerebral blood flow, which is probably due to a change of pH rather than PCO_2 , and is associated with significant cerebral hypoxia. Cerebral blood flow is linearly related to PaCO_2 , and there is a 2% reduction of arterial blood flow for each 1 mmHg decline in PaCO_2 . This means that severe HV leading to profound hypocapnia of 15–20 mmHg can reduce the cerebral circulation by approximately 50%. Hypocapnia can also cause abnormal esophageal motility and increases in tone in the muscles in the colon. Patients with known coronary vasospasm with or without significant fixed coronary artery obstructions can develop coronary vasospasm and reduced coronary perfusion following hypocapnia; this may be associated with the development of angina and ischemic electrocardiographic changes. Electroencephalographic recordings during HV often reveal paroxysmal or continuous high-voltage slow-wave activity of approximately $2\text{--}5 \text{ cycles s}^{-1}$.

Causes

HV can be caused by a number of factors, which often overlap and interact. Organic causes include a variety of factors such as drug effects (aspirin overdose), the early stages of alcohol withdrawal, respiratory disease such as asthma and pulmonary embolus, central nervous system disorders, and

chronic pain. Physiological causes include altitude acclimation, heat, and exercise. HV is also induced by speech, and progesterone in women reduces PaCO_2 by up to 8 mmHg in the second half of the menstrual cycle and even lower during pregnancy. Psychological factors include anxiety, depression, and panic attacks, but the relationship between anxiety and breathlessness is not simple.

Clinical Features

HV is clinically significant only if it results in physical complaints that are distressing or disabling. The way in which these symptoms are produced and interpreted is important in understanding why HV becomes a problem for some patients. A knowledge of the physiology suggests that the clinical manifestations of HV may be diverse and can involve almost any system in the body. For this reason, HV is said to have replaced syphilis as the great mimic in medical practice. No symptoms are truly specific for HV, but certain patterns are discernible. Common neurological complaints include dizziness, syncope, and tingling of the hands and feet (paresthesia), which may be unilateral and mimic a stroke; respiratory complaints include sensations of breathlessness or the inability to take a satisfactory breath (air hunger); cardiovascular manifestations are commonly chest pains often mimicking angina, palpitations, and racing pulse; gastrointestinal complaints include air swallowing (aerophagy) resulting in a bloated sensation, flatulence, and heartburn; musculoskeletal symptoms include muscle aches (a consequence of increased muscle tone with muscular tightness) and tetany (extremely rare); and general symptoms may include chronic and easy fatigability, weakness, the sensation of feeling cold, and poor concentration.

Although symptoms can be described in terms of organs and systems, it is probably more useful to divide them into those due to an increase in neuronal excitability; those due to a constriction of the blood vessels, especially in the cerebral, coronary, and skin circulations; and those of uncertain cause.

The Hyperventilation Syndrome

The term hyperventilation syndrome, first proposed in the 1930s, came under attack in the 1990s, and it was recommended that it be abolished. The reasons for this proposal were that (1) there were no established valid criteria, (2) the HV provocation test (designed to reproduce symptoms in patients with the syndrome) was found to be unreliable, (3) it is often impossible to establish the diagnosis in the absence of demonstrated hypocapnia, and (4) the link

between panic attacks and HV was found to be tenuous. Because most symptoms reported by patients did not require a fall in PaCO_2 , other terms such as dysfunctional breathing were suggested as an alternative. This umbrella term allows the inclusion of patients with and without HV, and it moves the focus of attention from physiological hypocapnia to a more pragmatic clinical approach.

Patients with dysfunctional breathing have an unsteadiness of breathing in response to stimuli such as exercise and a period of voluntary overbreathing, increased respiratory rate, abnormal orthostatic increases of respiratory gas exchange, predominantly intercostal respiratory effort, and frequent sighing. But not all patients with dysfunctional breathing hyperventilate or have hypocapnia.

The diagnosis of dysfunctional breathing can be difficult because the overbreathing aspect of the symptom complex may be episodic and difficult to demonstrate. The characteristic symptoms are common to other diseases, and there is no standard diagnostic test. This may lead to the underrecognition of the effects of abnormal breathing patterns, and symptoms may be wrongly attributed to other causes, resulting in inappropriate investigations and ineffective treatment, specially in patients with coexisting lung disease.

Establishing the Diagnosis of Hyperventilation

HV can coexist with other disorders, and it is important to decide which, if any, of the patient's symptoms could be due to HV. In particular, HV should be considered in any patient with a long history of unexplained physical symptoms involving a number of different organ systems.

Acute HV may be obvious from the fast rate and increased depth of breathing accompanied by the constellation of symptoms of hypocapnia. Because the disorder may be intermittent, however, a low PaCO_2 is not diagnostic; spot arterial or end-tidal samples may be normal. Conversely, making the measurement can induce overbreathing. Ambulatory transcutaneous measurement of PCO_2 for continuous monitoring is not yet responsive enough to be clinically useful, but it has led to important findings in recent research studies of *in vivo* panic attacks. End-tidal PCO_2 is sometimes measured uninvvasively by capnograph sampling from a nostril as part of lung function testing; the reduction of PCO_2 at rest, or during or after various provocations such as exercise, may suggest that symptoms are related to HV.

A commonly employed test is the HV provocation test (HVPT); the patient is asked to hyperventilate for

3 min (with concomitant monitoring of end-tidal PCO_2) and to keep PCO_2 below 20 mmHg for at least 1 min. After 3 min, the patient completes a checklist of symptoms experienced during overbreathing. Although this test has limitations (as previously mentioned), it is often used as a diagnostic aid and has some clinical utility, especially when the physician is attempting to help the patient reattribute physical symptoms to HV (and not some imagined sinister disease). Because there is no widely accepted and reliable diagnostic test, the incidence of HV has probably been underestimated.

Hyperventilation and Its Relation to Anxiety and Panic

Similarities have long been noted between the symptoms of panic attacks and HV. It has recently been established that CO_2 inhalation (and to a lesser extent HV) causes more anxiety and panic in patients with panic disorder than in normal controls. One theory proposed to explain this phenomenon is that the respiratory drive in panic disorder patients is controlled by abnormally sensitive CO_2 receptors in the central nervous system. Klein suggested that panic disorder patients possess an abnormal suffocation detector that processes asphyxia-related causes. According to Klein, HV among panic disorder sufferers is a result of the body's adaptive attempts to reduce panicogenic CO_2 . That is to say, chronic HV and sighing may adaptively keep PCO_2 below a depressed suffocation alarm threshold. The nature of the specific respiratory abnormality in panic disorder remains controversial, however, and investigators disagree on the interpretation of recent experimental data. Whereas some authors have interpreted biological challenge data as supporting a biological etiology for panic disorder, other investigators have argued that psychological factors (e.g., perceived safety, perceived control, or proximity to a safe person in the laboratory) mediate patients' responses to these challenges and that cognitive theories of panic disorder can account for these findings.

Recent work with ambulatory monitoring of CO_2 has failed to confirm the view that HV is a necessary factor for panic to occur. Although hypocapnia has been demonstrated to occur during a spontaneous panic attack in the laboratory, in a recent study there was a decrease in PCO_2 in only 1 of the 24 registered panic attacks that lasted 3 min, and even during this attack the degree of HV was not impressive. It is not possible, however, to discount a role for HV in the production of symptoms experienced during panic attacks. The crucial link between HV (when it occurs) and panic may be cognitive; panic attacks

occur when the bodily and mental sensations accompanying HV are interpreted as signs of impending personal catastrophe, such as madness or heart attack (see [Figure 2](#)).

Chronic Hyperventilation

An initial attack of HV caused by a combination of physiological, psychological, and possibly pathological factors could create a vicious circle and lead to increasing anxiety and further HV. The patient may misattribute the first attack of HV to serious disease and then perpetuate the disorder by becoming more anxious and breathing more deeply to relieve chest discomfort. CO₂ homeostasis is then reset at a lower level. Such a sequence could rapidly lead to invalidism and chronic HV. In these patients, PCO₂ is either chronically low at rest and throughout a number of provocations or only mildly reduced at rest but precipitated into prolonged reduction by either exercise or voluntary overbreathing.

Hyperventilation, Panic, and Asthma

The prevalence of anxiety disorders (including panic) is above expected levels in patients with asthma, and asthma is more common in people with psychiatric illness. The relationship appears strongest in those

with severe asthma and those with severe anxiety. Panic and anxiety can directly exacerbate asthma symptoms through HV.

In a recent longitudinal study, it was found that active asthma predicted subsequent panic disorder and that panic disorder predicted subsequent active asthma, this effect being stronger in women and in subjects younger than 30 years old. This relationship between physiological and psychological factors in asthma offers opportunities for research.

Management of Hyperventilation

The main aim of treatment is to reassure patients that they do not have a serious life-threatening illness and then to treat the underlying cause of the HV. If no cause is found or the cause is untreatable, it is often possible to teach patients to understand and adjust to the symptoms.

First, organic causes for the presenting symptoms (e.g., asthma or pulmonary embolus) should be excluded. Two of the main treatments used in the management of patients with HV-related symptoms in recent years have been breathing retraining and cognitive reattribution of physical symptoms to HV. Breathing retraining involves encouraging the patient to breathe in a slow regular fashion using the diaphragm; reattribution is aimed at helping the patient

Figure 2 Principal components of the cognitive model of panic attacks in which hyperventilation is involved in the production of symptoms.

to ascribe the physical symptoms to anxiety and at explaining the relationship between stress and HV. In practice, however, it is very difficult to determine the relative contributions of these two therapeutic components to outcome.

Recent research supported the view that training in controlled breathing is not of specific benefit in patients identified as hyperventilators by the provocation test. Indeed, breathing retraining has been referred to as a rational placebo that is effective not by restoring levels of CO₂ but by inducing relaxation, providing a structured task and distraction, and giving the patient a sense of control and mastery. This may distract the patient from feelings of anxiety and promote self-reliance.

Breathing Exercises and Asthma

It has been reported that up to 30% of adults with asthma in the community may have symptoms suggestive of functional breathing disorders, and there is some evidence of a role for breathing exercises in the treatment of asthma complicated by these abnormal breathing patterns. A review of psychotherapeutic interventions for adults with asthma found conflicting evidence, however, with some positive studies but with insufficient data to draw firm conclusions.

Historical Background

Induction of Hypnosis

Hypnotizability Assessment and the Phenomena of Hypnosis

Hypnotic Interventions for Stress Management

Conclusion

Glossary

Hypnotic induction

A series of suggestions that focus attention and bring about the transition from ordinary waking experience to hypnosis.

Hypnotizability

The potential to experience hypnosis; a relatively stable trait that varies from person to person and that can be assessed by standardized test procedures.

Nonspecific effect

A therapeutic outcome (e.g., symptom relief) that follows a hypnotic procedure but that occurs regardless of the patient's ability to experience deep hypnosis.

Historical Background

Special healing properties have been ascribed to trancelike conditions throughout civilizations and

time. Some of the earliest examples can be traced back 4000 years to ancient Egypt and by the 5th century BC to the Greek empire. The priests of these times established healing sanctuaries or sleep temples, where people suffering from mental or physical problems could seek relief. In exchange for some sacrifice or atonement, the priest or priestess performed incantations and rituals designed to heighten suggestibility and promote a trancelike sleep, during which the individual's dreams could be affected by healing communications from the gods. Similarly, witchcraft practiced during the Middle Ages, exorcisms to alleviate demonic possession, Afro-Caribbean voodoo rituals, and faith-healing in relatively modern times each appear to involve elements of what is today subsumed by the term hypnosis.

Historically, explanations for the effectiveness of many of these practices appealed to supernatural or metaphysical causes. More modern perspectives arose from controversies surrounding the work of the Austrian physician, Franz Anton Mesmer (1734–1815) and his followers. Working in France at the time of the American Revolutionary War, Mesmer observed that some patients derived benefit from the passing of magnets over their bodies. In due time, Mesmer concluded that he, himself, possessed the critical animal magnetism, a putative fluid within the body that, in combination with certain accoutrements, could be transferred to others as needed to heal them. This claim expressly identified the source of the healing power as a property of the magnetizer. Indeed, one of Mesmer's students, the Marquis de Puysegur, claimed to have successfully magnetized a tree on his estate, where some of his peasant workers obtained relief from their ailments. Eventually, de Puysegur found that he could influence the behavior of mesmerized patients merely by talking with them, much the same way that hypnosis is used today. The fluid theory of animal magnetism was soon discredited, however, in a series of investigations conducted by such scientific luminaries as Benjamin Franklin and Antoine-Laurent Lavoisier (1784). Nevertheless, the therapeutic effects – at first dismissed as the products of imagination and suggestion – were too striking to be ignored for very long.

By the 1840s, the current term hypnosis had been coined by James Braid, a surgeon from Edinburgh, Scotland, who conceptualized the process as one of focusing attention, leading ultimately to a state of artificial sleep. Subsequently, demonstrations of its analgesic uses in surgery – many by James Esdaile, a physician employed by the East India Company in Calcutta – were being documented in British medical periodicals. It was not long before hypnosis was adopted for use in the treatment of psychiatric and

neurological disorders following a number of celebrated cases by such renowned academics and physicians as Hippolyte Bernheim, Jean-Martin Charcot, Sigmund Freud, Pierre Janet, and Morton Prince. Today, hypnosis is commonly employed in clinical practice as an adjunctive psychological technique for the management of a variety of conditions, both acute and chronic, such as pain, anxiety, addiction, mood disturbance, dissociative disorders, and stress-related disorders.

Induction of Hypnosis

A typical hypnotic induction begins with the establishment of rapport between the hypnotist (sometimes referred to as the operator) and the to-be-hypnotized person (the subject). This serves not only to assure the subject of the hypnotist's competence and trustworthiness, but also to create a favorable expectation for a positive response to hypnosis (i.e., by explaining how hypnosis will be used with the subject and correcting any misconceptions about the procedure the individual may have). After this, the subject is invited to relax and be comfortable and to pick some target on which to fix his or her gaze. The hypnotist then exhorts the subject to experience a growing feeling of relaxation and proceeds to direct attention to simple, suggested perceptual changes (e.g., "Your eyelids are becoming heavier and heavier. . . they will soon shut of their own accord. . ."). The specific suggestions are often designed to take advantage of normal bodily responses to the situation, such as the strain and fatigue associated with prolonged visual fixation. Because most individuals readily share such experiences and respond successfully, judiciously selected suggestions of this sort may also serve to enhance expectations for further responsiveness to hypnosis. Once eye closure has been accomplished, the hypnotist will often test whether the subject is truly beginning to experience the condition of hypnosis or is merely complying. Thus, the hypnotist may suggest that it is becoming increasingly difficult, perhaps impossible, for the subject to lift his or her hand. The majority of subjects who pass this challenge (i.e., fail to lift their hand) are indeed usually capable of positive responses to a number of ensuing hypnotic suggestions, provided they are administered in a generally graded sequence of increasing difficulty.

Often early suggestions attempt to promote subjective alterations involving sensory and motor responses, such as the hand growing lighter and lighter and beginning to float upward from the armrest of the subject's chair. Coupled with complementary remarks that as the hand rises the subject will sink deeper and deeper into hypnosis, such a relatively easily experienced suggestion is but one of several deepening techniques

intended to shift the subject's awareness from the subject's ambient surroundings to a nearly exclusive focus on experiencing the hypnotist's suggestions. At this point, a suitable subject may experience marked distortions of perception, memory, and mood in response to carefully and methodically linked suggestions that are appropriate to the individual's level of hypnotic skill.

Hypnotizability Assessment and the Phenomena of Hypnosis

Contrary to the view, espoused by the eighteenth-century mesmerists and many modern-day stage hypnotists, that the power of hypnosis resides in the influence of the hypnotist, the scientific evidence is compelling that only a subset of people are capable of experiencing the full range of phenomena that constitute the domain of hypnosis. Thus, it is clear that the ability to respond to hypnosis is determined, in large part, by the individual about to undergo the procedure.

Formal attempts to measure hypnotic ability and to quantify aspects of hypnotic experience began in the United States in the 1930s. The most popular hypnotizability scales in use worldwide today were derived from efforts by Andre Weitzenhoffer and Ernest Hilgard of Stanford University in 1959. A tape-recorded adaptation of their Stanford Hypnotic Susceptibility Scales (SHSS), suitable for use with groups of individuals, was published in 1962 by Ronald Shor and Emily Carota Orne of Harvard University and is known as the Harvard Group Scale (HGS). The general design of these instruments includes a standardized induction and order of administration of hypnotic suggestions that is characterized by increasing difficulty over the course of 12 items. A person's hypnotizability is determined by the number of suggestions (which can range from 0 to 12) that evoke positive behavioral responses as judged by the hypnotist (SHSS) or by the subject (HGS). With the development of standardized scales for hypnotizability assessment, researchers have been able to identify three distinct clusters of hypnotic phenomena.

1. **Ideomotor responses.** One type of hypnotic response that nearly all individuals can experience to some degree is the tendency for vividly imagined bodily movement to produce corresponding physical movement on a seemingly involuntary basis. Such is the case, for example, when a subject responds to suggestions that his or her "forearm is beginning to feel lighter . . . as if a large helium-filled balloon is attached to the wrist and is gently lifting the arm . . . allowing it to float effortlessly upward and upward. . . ." Response

to ideomotor suggestions can also occur in the absence of prior hypnotic induction, indicating that some degree of suggestibility may also operate under normal waking conditions. However, although waking suggestibility is moderately correlated with hypnotic responsivity, evidence shows that the hypnotic induction procedure contributes to hypnotic outcomes. Thus, it is exceedingly rare for an individual to respond to suggestions in the waking condition and fail to respond following induction; on the other hand, many individuals' responsiveness to suggestion is substantially increased following an appropriate hypnotic induction.

2. **Challenge suggestions.** Challenge items are intended to create a contradictory subjective experience involving the inability to carry out one's own will. For instance, the hypnotized subject might be told to "interlock your fingers tightly . . . so tightly that they will be impossible to separate. In a moment, you may wish to try to separate your fingers, but you will find that you are unable to do so. Go ahead . . . try . . . just try to pull your fingers apart." If successfully passed (e.g., in this case, the fingers do not separate), challenge suggestions provide a compelling impression of external control over the individual's behavior – an impression that is often shared by the hypnotized person and onlookers.

3. **Cognitive/perceptual alterations.** Among the more difficult hypnotic suggestions are those designed to induce some kind of perceptual hallucination and those intended to alter the ability to remember personal experiences from the immediate or remote past. Hallucinatory suggestions can be either positive, in which a nonexistent stimulus is introduced by the hypnotist (e.g., it is suggested that a mosquito is buzzing annoyingly around the subject's face), or negative, in which an actual physical stimulus loses its perceptibility (e.g., the subject is told that he or she will be unable to smell anything, after which an open bottle of ammonia is passed under the nose). Suggested amnesia is an example of a commonly administered cognitive suggestion, whereby the subject is instructed that, on awakening, he or she will have no recollection of the events that transpired during the hypnotic proceedings. Similarly, posthypnotic suggestions are sometimes given during hypnosis with the intent that, following termination of hypnosis, the subject will perform a specific behavior in response to a prearranged cue but will not remember being told to do so. When properly used with suitable patients, amnesia and posthypnotic suggestions can be important clinical tools that may extend therapeutic gains outside the therapist's office.

In addition to delineating the general factor structure of hypnosis into ideomotor, challenge, and

cognitive domains, the use of standardized assessment scales has resulted in a great deal of information about hypnotizability in general. One important feature, from both clinical and research perspectives, is the manner in which hypnotizability is distributed in the general population. Hilgard and his associates found that hypnotizability, like many other human skills, follows a normal or bell-shaped pattern, in which the majority of people have the capacity to experience most hypnotic phenomena to some degree, 15–20% are generally unresponsive, and an approximately equal percentage of people are highly responsive. Recognition of such individual differences in the ability to respond to hypnotic procedures is an important consideration for its use clinically, particularly when treatment is predicated on a successful response to difficult cognitive suggestions, such as to experience analgesia (a negative hallucination) for either acute (e.g., dental) or chronic (terminal-stage cancer) pain.

Although scores on standardized assessment scales prove useful in predicting the types of hypnotic suggestions that individuals are most likely to experience, they are not absolute prognosticators of hypnotic potential. This is because, for individuals with scores in the moderately hypnotizable range, various combinations of passed items from different realms of difficulty are possible. The hypnotizability score is determined merely by the sum of items that are passed, not by their classification as ideomotor, challenge, or cognitive (which corresponds roughly to their difficulty level). Thus, although there is virtual assurance that a subject with a score of 2 (out of a possible 12 points) will be unable to experience a positive hallucination, the same cannot be said of a subject with a score of 5 or 6. Modifications of the original SHSS have been published to identify and characterize individual hypnotic profiles, but their use has been limited primarily to research purposes.

A final yet particularly important observation made possible by the availability of standardized scales of hypnotic ability is the general stability of an individual's hypnotic potential over time. This has been confirmed in numerous laboratories throughout the world using correlations among scores obtained for the same participants at varying test–retest intervals, in some cases spanning several decades. Although some research suggests that environmental circumstances can occasionally increase a subject's responsiveness to hypnotic suggestion (e.g., situations involving extreme sensory deprivation or explicit training in the skills necessary to respond positively to specific suggestions), the overall consensus of the evidence is that hypnotizability is one of several relatively enduring characteristics of an individual's personality.

Hypnotic Interventions for Stress Management

Although hypnosis is widely regarded as an effective cognitive-behavioral method for alleviating stress, there is surprisingly little formal research on this issue. There are, however, numerous clinical and experimental studies concerned with specific problems that are often regarded as stressors. From this kindred literature, we can extrapolate conclusions pertaining to the effectiveness of hypnotic techniques in reducing stress. Before doing so, however, it seems prudent to characterize the type of stress to which we refer.

Conceptualizations of stress vary widely. Some investigators have identified stress primarily as a stimulus in which some aspect of the physical or psychological environment exacts a toll on individuals and/or society; others view stress as the psychological or physiological response to such hostile environmental provocation; and still others embrace a more dynamic view whereby the individual's appraisal of the specific environmental pressures, his or her own coping resources, and available options all converge to determine the nature and extent of the stressful experience. From the perspective of scientists and practitioners concerned with the use of hypnotic interventions for stress management, each of these variant emphases holds viability. This is because hypnosis is one of the few psychological techniques that, given an appropriately responsive individual, can be introduced at various points to modify the experience of stress. Thus, it has the potential to mitigate the stimulus impact of a stressor by altering perceptual experience. It can also be enlisted to modify cognitive and affective factors that influence a subject's appraisal of the stressor and his or her ability to cope. In addition, hypnosis may provide specific relief of symptoms precipitated or maintained by exposure to stress.

Pain Control

The use of hypnosis to suppress pain provides dramatic evidence of the technique's value for stress management. Although the widespread availability and safety of chemical anesthetic agents today obviates the use of hypnosis as a general method of surgical anesthesia, there are numerous documented cases in which hypnotic techniques were effectively employed as the sole anesthetic for surgery (e.g., limb amputations, temporal lobectomy, cardiac surgery, tooth extractions, appendectomies, and cesarean sections, among others). An important caveat, however, is that the effectiveness of hypnosis in blocking instances of acute pain is often correlated with the patient's ability to be hypnotized. This has been demonstrated in both clinical samples of patients undergoing painful

medical procedures (e.g., bone marrow aspirations, lumbar punctures, and debridement and dressing of burn wounds) and experimental studies involving painful laboratory stressors (e.g., prolonged immersion of the hand in ice water). Another feature that may contribute to the efficacy of hypnosis in the control of acute pain in hypnotically responsive people is the use of direct suggestions delivered in a heterohypnotic or self-hypnotic context.

Hypnosis is decidedly less helpful in the management of certain forms of chronic pain, particularly those with a psychogenic component. Two issues are relevant here. The first concerns the impracticality of heterohypnotic treatments based on direct suggestion in blocking the experience of persistent chronic pain, most of which occurs outside the therapist's office. The alternative strategy, training in self-hypnosis, often requires regular contact with the therapist to reinforce its continued use by the patient in his or her daily life. The more formidable problem, however, concerns the powerful reinforcing value that pain behavior can acquire among family, friends, and other important members of the community. Thus, the sympathy and support provided by others – the so-called secondary gains – may serve to maintain the individual's pain and undermine the incentive to practice hypnotic techniques that otherwise might be helpful in bringing about relief. The most promising prognosis for patients suffering from functional pain of this nature is achieved by a combination of behavior therapeutic principles aimed at extinguishing pain behavior and the implementation of hypnotic or self-hypnotic approaches to minimize pain-related discomfort.

For other forms of chronic pain that do not involve a substantial functional component (e.g., pain from shingles, trigeminal neuralgia, and many types of cancer), hypnosis and self-hypnosis have proven useful as an adjunct to long-term pain management programs. Hypnosis, even self-hypnosis, derives much of its benefit from the interpersonal relationship between patient and therapist, which, among other consequences, tends to shape expectations for therapeutic improvement. In an appropriately supportive context, therefore, hypnotic techniques may prove beneficial without particular regard to the patient's overall ability to respond to hypnosis. For example, we have observed significant improvement among children and adolescents during the course of an 18-month intervention involving regular group training in self-hypnosis to control unpredictable episodes of pain associated with sickle-cell disease. Prior to the intervention, many of the children experienced frequent absences from school, occasionally for weeks

at a time, and the only treatments available included analgesics, narcotic medications, and hospitalization. Although the participants were enrolled in the study based on their expressed wish to help identify an effective nonpharmacological treatment for the disease and without regard to hypnotic ability, our findings indicated that, in this case, the ability to respond to hypnotic suggestion was not an overriding factor in determining how often self-hypnosis was practiced nor how beneficial it proved to be. Apparently, self-hypnosis training, along with consistent reinforcement of the technique during the regular group sessions, provided a much-needed coping skill; the group treatment sessions themselves were critical to maintaining motivation and providing a forum for the patients to share their common fears, misunderstandings, and concerns, which were not being adequately addressed by conventional medical management systems. For the group as a whole, the combination of these therapeutic approaches led to increased school attendance, improved nighttime sleep, less dependence on medication, and fewer bouts of pain, although the more severe episodes of pain still required nonhypnotic supplements for pain management.

Anxiety and Stress Disorders

Stress is inextricably linked to anxiety states, whether they are circumscribed by some anticipated source of realistic concern (e.g., impending open-heart surgery), are more persistent but specific fears (e.g., of elevators or spiders), or are unrelenting and pervasive hindrances to normal functioning (e.g., agoraphobia or social phobia). Hypnotic techniques have proven extremely effective in treating anxiety conditions. Available evidence suggests that there may be two distinct mechanisms responsible for the high success rate. The first, which is nonspecific to hypnosis, is the tendency for hypnotic induction to promote a profound state of relaxation and comfort in many individuals, regardless of their hypnotic capacity. As Joseph Wolpe demonstrated in his development of a behavior therapeutic approach to the treatment of anxiety disorders, relaxation is incompatible with fear. Thus, the cultivation of extreme relaxation, whether accomplished with hypnosis, self-hypnosis, or some other cognitive-behavioral technique (e.g., autogenic training, meditation, or progressive relaxation), will tend to inhibit symptoms of anxiety. The second mechanism is directly related to the ability to experience hypnotic-like conditions and applies to some of the more severe forms of anxiety and trauma-related disorders. Fred Frankel (Harvard Medical School) has compiled extensive data from case studies, which suggest that high hypnotizability may be a

risk factor for the development of phobic anxiety. The same positive association involving hypnotizability has been found for acute stress disorder, posttraumatic stress disorder, and dissociative disorders following traumatic experiences. Although such evidence appears to suggest that highly hypnotizable people may be more vulnerable to developing severe anxiety and stress-related conditions pursuant to adverse life events, the picture is far from clear. To date, the majority of studies that report such a relationship have employed cross-sectional designs, meaning that hypnotizability is measured only at the time (or shortly after) the patient is diagnosed with a particular disorder. Thus, it is unknown whether high hypnotizability constitutes a predisposition to anxiety and dissociative symptoms in the aftermath of trauma or whether it is one of several consequences of the stressful experience. In support of the latter possibility, several studies have shown that hypnotizability may be enhanced under adverse conditions, such as sensory deprivation or restricted environmental stimulation. Only studies that adopt a prospective, longitudinal design, in which hypnotizability assessments occur both before and after a stressful life event, can determine the role of hypnotizability in the causal sequence leading to stress-related psychopathology. Nevertheless, and most important, the same highly hypnotizable people who may appear to exhibit a propensity to develop anxiety and stress-related disorders also benefit markedly from psychotherapy that involves the use of hypnosis and training in self-hypnosis as a coping strategy. Similarly, hypnotic methods have been successful in treating survivors of trauma whose symptoms of hyperarousal, emotional numbing, and avoidance are maintained by uncontrollable intrusive flashbacks and recurrent nightmares. In the treatment of posttraumatic stress disorders, hypnosis is most effectively employed as an adjunctive technique, secondary to pharmacotherapy and/or supportive psychotherapy. On a cautionary note, however, the heightened suggestibility and vividness of the imaginings that hypnotized individuals often experience have been associated with a corruption in the accuracy of recollections obtained during hypnotic interviews, whereas their confidence that such memories are veridical tends to be increased. Thus, current evidence warrants that clinical professionals carefully evaluate how hypnosis should be used in the treatment of victims who claim full or partial amnesia for details of past traumatic experiences. As a relaxation technique, hypnosis and self-hypnosis can be highly beneficial; as a tool for recovering memories of past life events, hypnosis elevates the risk that believed-in, false memories may emerge.

Psychophysiological Disorders and Psychoneuroimmunology

Stressors trigger specific neuroendocrine and sympathetic nervous system responses, which, if prolonged, can lead to a number of clinical manifestations linked to parasympathetic inhibition, including dysregulation of respiratory, cardiovascular, digestive, eliminative, and sexual functions. An abundance of case studies attests to the value of hypnotic and self-hypnotic procedures in the treatment of such conditions as asthma, tension headache, irritable bowel syndrome, Crohn's disease, and insomnia. However, there is a paucity of controlled studies in which the distinctive contributions of hypnotic responsiveness and placebo factors to clinical improvement can be evaluated. The available evidence suggests that hypnosis may be as effective as related methods (e.g., biofeedback and progressive relaxation) aimed at countering sympathetic arousal in the treatment of psychophysiological disorders. The mechanism of action appears to involve the induction of a profoundly relaxed condition, which can be achieved in a majority of individuals regardless of their capacity to respond to hypnotic suggestion.

Recent molecular and pharmacological studies have identified intricate patterns of communication between the immune system and the central nervous system, which gives substance to the long-held belief that stress can precipitate illness. Hypnosis is a versatile psychological approach that can alter the perception, evaluation, or symptoms of stress and that might therefore prove effective in the management of infectious or malignant disease. Many studies have found that hypnosis is beneficial in reducing stress symptomatology, which may result in a corresponding improvement in immune function, but the benefit is often only weakly correlated with subjects' hypnotizability, suggesting that any immune enhancement related to hypnosis may be due to nonspecific effects. However, in one study conducted by our laboratory, we were able to confirm a relation between ratings of the depth of relaxation and increases in both the number and cytotoxic capacity of natural killer cells from whole-blood samples from medical students trained to manage stress using self-hypnosis. Other investigators have reported findings that suggest a relationship between the practice of hypnotic methods and indices of humoral and cellular immunity. In addition, recent studies by Gruzelier and colleagues in Great Britain have identified a positive association between hypnotizability and several indices of immunocompetence, which was most evident when hypnotic procedures included guided imagery that specifically addressed immune system dynamics.

At present, we can conclude only that hypnotic techniques appear to be effective in promoting well-being and reducing reactivity to stress, which might otherwise impair immunity to disease. The development of optimal strategies for the use of hypnosis to counteract stress-related immune compromise continues to be informed by further investigation.

Conclusion

As with any clinical intervention, hypnosis can lay claim to the efficacy of both specific and nonspecific components. Because the benefit from hypnotic therapy is a function of the treatment itself, as well as the patient's ability to experience hypnosis, several processes may operate independently or synergistically to determine therapeutic outcome. For individuals who are able to profoundly experience hypnotic suggestion, the stimulus, evaluation, or symptom features of a stressor can be directly addressed in treatment, and the same individuals may be able to avail themselves of the additional benefits that accrue from generalized relaxation and positive expectancies. For individuals of lesser hypnotic capacity, the non-cognitive aspects of hypnosis, particularly relaxation, clearly provide an effective technique for inhibiting sympathetic arousal. Finally, because hypnosis requires the establishment of a strong and trusting therapeutic alliance between the therapist and patient, mutual expectations regarding milestones for improvement, coupled with regular contact, may serve to enhance motivation sufficiently to assure adherence to treatment protocols. For some instances of stress, the ability to experience hypnosis may be paramount to effective coping, whereas, for other

stressors, simply the subject's belief in his or her ability to benefit from the exercise may prove helpful. It must be emphasized, however, that individuals seeking treatment with hypnosis should consult with a qualified physician, psychologist, or dentist who, in addition to advanced training and practice in one of these health-care specialties, has skills in the adjunctive therapeutic use of hypnotic techniques. When properly applied, hypnotic methods can have a beneficial role in the prevention and treatment of stress-related disorders.

Glossary

Cortisol

Glucocorticoid hormone synthesized and secreted from the adrenal cortex in primates. Cortisol is secreted in a diurnal rhythm, and its secretion is increased in response to acute stress. Cortisol controls hypothalamic-pituitary-adrenal axis activity through negative feedback inhibition and exerts metabolic, immune-regulatory, and behavioral effects that adapt the organism to stress.

<i>Functional somatic syndromes</i>	The presence of multiple physical symptoms that manifest without identifiable physical signs or medical abnormalities. Specific symptoms or symptom patterns are used to define syndromal disorders, such as chronic fatigue syndrome, fibromyalgia, irritable bowel syndrome, and chronic pelvic pain.	the person or others and a response of intense fear, helplessness, or horror.
<i>Glucocorticoid receptors</i>	Intracellular receptor molecules through which cortisol exerts its effects on target cells. There are two types of receptors, the mineralocorticoid receptors (MRs) and the glucocorticoid receptors (GRs). MRs are mainly located in the hippocampus, whereas GRs are widely distributed throughout the brain and periphery. During stress, MRs and GRs in concert control hypothalamic-pituitary-adrenal axis activity.	
<i>Hypothalamic-pituitary-adrenal (HPA) axis</i>	Neuroendocrine cascade that controls the secretion of glucocorticoids during stress. Corticotropin releasing hormone from the paraventricular nucleus of the hypothalamus stimulates the secretion of adrenocorticotrophic hormone from the anterior pituitary, which in turn stimulates the production and secretion of glucocorticoids (corticosterone in rodents, cortisol in primates) from the adrenal cortex.	
<i>Negative feedback inhibition</i>	A decrease in HPA axis activation in response to increasing levels of circulating glucocorticoids, and vice versa, mediated through glucocorticoid receptors at the hippocampal, hypothalamic, and pituitary levels. The feedback sensitivity of the pituitary can be determined by measuring cortisol suppression in response to the synthetic glucocorticoid dexamethasone. Standard doses of dexamethasone detect nonsuppressors (feedback resistance), whereas low doses detect hypersuppressors (increased feedback sensitivity).	
<i>Posttraumatic stress disorder (PTSD)</i>	An anxiety disorder that manifests secondary to the experience of a traumatic event and that is characterized by symptoms of reexperiencing of the event, avoidance of reminders of the event, and hyperarousal. Symptoms must last 1 month or longer and must be associated with significant impairment in work, family, or social functioning.	
<i>Stress</i>	A state caused by real or perceived challenge to homeostasis, which is accompanied by a hormonal response.	
<i>Trauma</i>	A stressful experience that involves actual or threatened death or serious injury or a threat to the physical integrity of	

Since the seminal studies by Hans Selye in 1936, stress has been associated with the activation of the hypothalamic-pituitary-adrenal (HPA) axis, ultimately resulting in the increased secretion of cortisol from the adrenal glands. The physiological effects of cortisol help the organism to maintain homeostasis under conditions of stress. The association between stress and increased cortisol secretion has been consolidated over the past decades to such an extent that stress and increased cortisol secretion nearly have become synonyms in the literature and, moreover, the presence of cortisol hypersecretion has been used to define states of stress. However, representing a major challenge for current concepts in stress research, an increasing number of studies have now provided convincing evidence that the adrenal gland can be hypoactive in some stress-related states. The landmark studies in the 1990s by Rachel Yehuda and her group on neuroendocrine dysregulation in posttraumatic stress disorder (PTSD) have catapulted the phenomenon of hypocortisolism into the center of neuroendocrine stress research. The phenomenon of hypocortisolism has since received growing attention. In fact, hypocortisolism does not merely represent a specific correlate of PTSD but has also been observed in response to severe acute, chronic, and developmental stress in both animal models and studies of human subjects. In addition, hypocortisolism has been observed in patients with chronic fatigue syndrome, fibromyalgia, and chronic pelvic pain, among other functional somatic syndromes. All these disorders are arguably related to stress and frequently coincide with mood and anxiety disorders, including PTSD. Although hypocortisolism appears to be a frequent and widespread phenomenon, its precise definition and epidemiology as well as its underlying mechanisms and physiological relevance remain speculative. It is also unknown whether there are independent or interactive genetic contributions to the manifestation of hypocortisolism in stress and illness. It has been suggested that hypocortisolism is causally involved in the pathophysiology of stress-related disorders; the persistent lack of the regulatory effects of cortisol may promote an increased vulnerability for the development of a spectrum of stress-related disorders characterized by fatigue, pain, stress sensibility, and anxiety. This model has important implications for the prevention and treatment of disorders related to hypocortisolism. This article summarizes current knowledge on the phenomenon of hypocortisolism in stress research.

What is Hypocortisolism?

There is no consensus on the definition of relative hypocortisolism in the published literature. In clinical endocrinology, the normal physiological range of urinary cortisol excretion is 20–90 $\mu\text{g day}^{-1}$. Thus, medical disorders of adrenal insufficiency, such as Addison's disease, are defined as an abnormal cortisol excretion below the normal physiological range, with endocrine challenge testing performed to elucidate the source of the insufficiency. Interestingly, adrenal insufficiency is related to fatigue, weakness, and pain. However, the stress-related phenomenon of hypocortisolism that is the focus of this article does not necessarily encompass cortisol secretion below the normal physiological range. Rather, reports of hypocortisolism in the stress literature refer to relative decreases of mean cortisol secretion in a defined study group compared to controls, with mean cortisol levels usually in the physiologically normal range. Thus, relative hypocortisolism as observed in stress-related conditions reflects subtle changes in HPA axis regulation that are uncovered when comparing groups. Consequently, to date, there are no diagnostic methods or normative values that allow us to decide whether an individual exhibits such relative hypocortisolism, independent of comparison subjects. When defining relative hypocortisolism, we must decide whether decreased cortisol levels should be measurable under basal conditions, during pharmacological dynamic testing, during stress challenge, or in all of these.

The most stringent definition of hypocortisolism might refer to decreased 24-h urinary cortisol excretion. On the other hand, certain tests, such as the adrenocorticotrophic hormone (ACTH)_{1–24} stimulation test, the corticotropin releasing hormone (CRH) test, or the low-dose dexamethasone suppression test, have the potential to be more sensitive to detect relative hypocortisolism by directly targeting the potential mechanisms of dysregulation, such as adrenocortical sensitivity and enhanced negative feedback sensitivity. However, blunted cortisol responses in a CRH stimulation test might not be readily interpreted as hypocortisolism, given that pituitary responses might be low due to elevated circulating glucocorticoid feedback and/or CRH receptor downregulation. Therefore, the identification of relative hypocortisolism usually requires the consideration of a pattern of neuroendocrine results across various conditions. The development of economic, reliable, and valid methods for detecting hypocortisolism as well as normative data is an important task for future research.

In sum, hypocortisolism may reflect many facets of neuroendocrine dysregulation, which may differ within and across populations, ultimately causing a

lack of cortisol effects in the organism. For the purposes of the following literature overview, hypocortisolism refers to a deficiency of cortisol, including (1) reduced basal cortisol secretion, (2) reduced adrenocortical sensitivity or capacity to challenge, or (3) enhanced negative feedback inhibition of the HPA axis. Reduced glucocorticoid signaling may also occur due to increased clearance or binding of free cortisol, as well as a reduced glucocorticoid sensitivity of target cells as a consequence of receptor abnormalities.

Clinical Findings of Hypocortisolism

Hypocortisolism has mainly been described in patients suffering from PTSD, chronic fatigue syndrome, fibromyalgia syndrome, and other functional somatic syndromes. Hypocortisolism also occurs in subsyndromal states of exhaustion and chronic pain.

Posttraumatic Stress Disorder

Because the development of PTSD by definition is related to extreme stress experiences, changes in neurobiological systems that participate in the mediation of the stress responses have been extensively studied in these patients. Paradoxically, initial studies demonstrated that basal cortisol concentrations, measured in urine or blood, were markedly reduced in combat veterans with PTSD compared to healthy controls. This finding has been replicated for Holocaust survivors with PTSD as well as for patients with abuse-related PTSD. Low basal cortisol secretion has been hypothesized to reflect hyperregulation of the HPA axis in the context of increased negative feedback sensitivity, as uncovered using low-dose dexamethasone suppression and metyrapone testing, although mild adrenal insufficiency might also play a role. In addition, findings of increased glucocorticoid receptor binding and function support the assumption of the increased negative feedback sensitivity of the HPA axis in PTSD. In the central nervous system (CNS), marked and sustained elevations of cerebrospinal fluid (CSF) concentrations of CRH have been reported in PTSD patients. Significantly, a circuit connecting the amygdala and the hypothalamus with the locus coeruleus, in which CRH and norepinephrine (NE) are the major neurotransmitters, participates in the regulation of vigilance, anxiety, and fear and in the integration of endocrine and autonomic responses to stress. Patients with PTSD exhibit markedly elevated CSF NE concentrations. Cortisol is known to inhibit the NE–CRH feedforward loop. Therefore, we might speculate that reduced cortisol availability leads to sensitization of the central stress responses,

with increased negative feedback acting at the pituitary level. Enhanced CRH and NE activation probably contribute to core symptoms of PTSD, such as sleep disruption, increased autonomic arousal, imprinted emotional memories, and enhanced startle reactivity. It must be noted that the finding of hypocortisolism has not been replicated in all PTSD studies, with both normal and elevated cortisol levels reported. Differences in type and timing of the trauma, symptom patterns, and comorbidity, among other factors, might contribute to this inconsistency. However, even normal cortisol output reported in some studies may be inappropriately low in the face of markedly elevated CRH-NE concentrations.

Chronic Fatigue Syndrome and Burnout

A large number of studies have investigated HPA axis alterations in chronic fatigue syndrome (CFS). Several independent studies reported decreased 24-h urinary free-cortisol excretion in patients with CFS. Although some studies failed to detect decreased cortisol secretion in CFS patients, a recent meta-analysis confirmed a moderate overall effect size for reduced 24-h urinary cortisol excretion in CFS. Studies of serial basal cortisol measures in saliva or blood over time have provided inconsistent findings. However, several chronobiological studies demonstrated lower amplitudes of cortisol in CFS patients when controlling for diurnal rhythm changes. CFS patients also exhibit decreased salivary cortisol awakening responses. In addition, decreased adrenal gland volume was reported for hypocortisolemic patients with CFS. In order to identify the origins of decreased adrenocortical activity in CFS, several studies have evaluated alterations in the sensitivity of the adrenal cortex to low doses of ACTH. Results are conflicting, with increased, normal, and decreased sensitivity reported. Inconsistent findings have also been obtained using pituitary or centrally acting challenge tests, such as the CRH challenge test and the insulin tolerance test. The only study that evaluated integrated HPA axis response to a psychosocial stressor found lower ACTH responses in CFS patients. In addition, there is one study suggesting the increased suppression of the HPA axis by a low dose of dexamethasone, although the effect was not confirmed at the pituitary level. Glucocorticoid receptor studies in CFS patients suggest decreased functionality. Taken together, although there is relatively solid evidence for relative hypocortisolism in CFS, results regarding the contributing mechanisms are inconclusive. Based on the concatenation of available findings, it has been suggested that hypocortisolism in CFS originates from the CNS rather than reflecting a primary adrenal dysfunction.

Regardless of its origin, hypocortisolism in CFS has been proposed to be directly linked to aberrations in the control of immune regulators, possibly leading to the characteristic symptom complex of fatigue, pain, cognitive disturbance, and sleep disruption.

Findings of hypocortisolism were also reported in nurses with burnout syndrome. In addition, a study of teachers with burnout syndrome, low morning cortisol, and hypersuppression of cortisol in response to a low-dose dexamethasone suppression test was reported. Such relative hypocortisolism was associated with physical complaints.

Fibromyalgia and Other Chronic Pain Syndromes

A series of studies have provided evidence for hypocortisolism in fibromyalgia syndrome (FMS). Three independent studies report reduced 24-h urinary cortisol excretion in patients with FMS relative to controls. Neuroendocrine challenge studies provided evidence for a primary adrenocortical impairment in FMS, although findings are conflicting. Patients with FMS also demonstrate reduced adrenocortical reactivity in the CRH stimulation test, with ACTH responses being either normal or increased. Several investigators have applied a standard dexamethasone suppression test to patients with FMS. Although two studies reported increased rates of nonsuppressors among FMS patients, several other studies revealed strikingly low rates of nonsuppressors in this patient population, rates that are even lower than nonsuppressor rates in healthy individuals. Nonsuppression seems to occur only in patients with comorbid depression. Based on these findings, we may expect that FMS is related to increased negative feedback sensitivity, similar to PTSD, although the hypothesis has not yet been directly tested. Despite the pronounced suppression of cortisol by dexamethasone, reduced glucocorticoid receptor affinity has recently been measured in the lymphocytes of patients with FMS, suggesting reduced regulatory effects of already low cortisol on target cells in the immune system, which might contribute to the increased perception of pain.

Findings of hypocortisolism have also been reported in women with chronic pelvic pain (CPP). In a series of studies of HPA axis function, women with CPP with no identified organic correlate demonstrated normal to low diurnal salivary cortisol levels. In response to CRH stimulation, normal plasma ACTH but reduced salivary cortisol concentrations were observed. These patients also exhibited an enhanced suppression of salivary cortisol to a low dose of dexamethasone, suggesting enhanced negative feedback sensitivity of the HPA axis. These same women had an increased rate of sexual and physical abuse experiences in addition to

PTSD and high levels of chronic stress. Interestingly, similar findings for women with CPP and verified pelvic adhesions were obtained. Evidence for relative hypocortisolism was also reported in other groups with chronic pain syndromes, such as patients with chronic headaches and children with recurrent abdominal pain. In addition, patients who had chronic sciatic pain 8 weeks after disk surgery exhibited decreased cortisol secretion after awakening, which was negatively correlated with pro-inflammatory cytokine activity. Significantly, a recent prospective study suggests that preoperative hypocortisolism predicts the development of persistent pain after disk surgery, as well as decreased pain threshold, increased NE activity, and pro-inflammatory cytokine production, in failed back syndrome (FBS) patients compared to patients who did not develop persistent pain and to healthy controls.

Other Somatic Disorders Related to Hypocortisolism

Relative hypocortisolism has also been reported for several other somatic disorders. Children and adults with asthma or atopic dermatitis exhibit decreased cortisol responses to psychosocial stress. Patients with rheumatoid arthritis have decreased basal cortisol levels, concordant with the assumption of hyperimmune activation in hypocortisolism. Basal hypocortisolism has been reported for atypical depression, which is characterized by lack of energy and predominantly somatic symptoms, closely resembling CFS. Finally, there is some evidence for low basal cortisol levels with blunted ACTH and cortisol responses to CRH challenge in patients with functional gastrointestinal disorders, such as irritable bowel syndrome (IBS). In IBS, the lack of cortisol effects might lead to the increased activation of CRH-NE systems, which in turn exert direct effects on gastrointestinal function, potentially leading to bowel symptoms.

Is There a Spectrum of Hypocortisolism-Related Disorders?

Hypocortisolism has been identified in diverse stress-related bodily disorders, although the potential mechanisms of hypocortisolism and its causal relationship in the pathophysiology of these disorders have not been sufficiently studied. Nevertheless, given the accumulating evidence for hypocortisolism in many patients suffering from diverse stress-related disorders, we may speculate that these disorders represent a spectrum of related disorders with common pathophysiological pathways. Interestingly, there is symptom overlap and high rates of comorbidity

among all the disorders related to hypocortisolism. There are also reports that cases with PTSD are at elevated risk for developing fatigue and pain over time. In addition, all these disorders share common risk factors, such as certain personality styles, chronic stress, and early adverse experience. Interestingly, the symptoms of all the disorders discussed so far are frequently triggered by acute or chronic stresses. Moreover, childhood abuse has been identified as a risk factor for the development of PTSD (after additional trauma in adulthood) as well as for CFS, FMS, CPP and functional gastrointestinal disorders. Although chronic stress and developmental stress have marked influences on the HPA axis, there are virtually no integrative studies assessing stress history and psychopathology together with HPA axis function in patients with bodily disorders. It is likely that stress experiences contribute to hypocortisolism in bodily disorders and might be linked to comorbid emotional problems. We next discuss whether there is preclinical evidence for an association between stress and hypocortisolism.

Stress and Hypocortisolism

Hypocortisolism does not seem to be an exclusive correlate of stress-related pathology; it has also been reported for healthy subjects living under ongoing stress as well as for healthy people with early developmental stress. In addition, some animal models of chronic and early-life stress have reported findings of decreased adrenocortical activity, particularly in nonhuman primates.

Studies in Humans

A small number of studies in humans suggest reduced adrenocortical activity or reactivity in states of chronic stress; some of these studies date back to the 1960s and 1970s. With increasing evidence for hypocortisolism in stress-related disorders, these early findings have regained attention in stress research. For example, decreased urinary excretion of the cortisol metabolite 17-hydroxycorticosterone (17-OHCS) was measured over several months in the parents of fatally ill children. Many of these parents demonstrated decreased 17-OHCS excretion below their initial baseline, even in phases of acute medical complications in their children. Lower than normal 17-OHCS excretion was also observed in soldiers of a special team in Vietnam who had been warned to expect an enemy attack; interestingly, 17-OHCS levels dropped even further on the day when the attack was anticipated. In another study, the same authors measured 17-OHCS excretion in helicopter medics in Vietnam. These

medics demonstrated a stable pattern of decreased 17-OHCS excretion whether they were flying or not. On flying days, some medics even demonstrated lower 17-OHCS levels than on their days off. Similar findings were obtained in civilian paramedics who demonstrated lower cortisol levels on work days compared to their days off. More recently, decreased plasma cortisol concentrations were measured in Bosnian prisoners of war, in white-collar employees with high work loads, and in chronically stressed teachers. Finally, evidence for marked hypocortisolism under basal conditions has been reported in severely neglected children, such as Romanian orphans. Maltreated children exhibit flat cortisol cycles throughout the day, particularly on high-conflict days. Interestingly, greater numbers of work hours for employed mothers and greater numbers of children in the household are also associated with lower morning cortisol levels and a flat cortisol cycle across the day in children. Decreased basal cortisol secretion and mild adrenocortical insufficiency in response to maximal ACTH stimulation has also been reported in adult women with histories of childhood sexual or physical abuse, particularly in the absence of depression. There are also findings of hypocortisolism in healthy subjects with early loss experiences. Taken together, these findings suggest that hypocortisolism does occur in humans as a function of severe chronic or early-life stresses. The physiological meaning of hypocortisolism is unclear; it might reflect a physiological state of preparedness in threatening situations, a state of exhaustion after chronic stress, and/or a state of adaptive counterregulation to hyperactive central stress response systems.

Animal Studies

The increasing evidence for the phenomenon of hypocortisolism in clinical and preclinical human research is not paralleled by an equal focus on hypocortisolism in animal models. Indeed, there exist only very few published studies that found low glucocorticoid secretion in animal models of stress. The most conclusive reports to date are studies in nonhuman primates. For example, when tested as adults, nonhuman primates exposed to prolonged periods of maternal or social deprivation exhibit marked behavioral, physiological, and neurobiological changes, including fearfulness and anxiety, social dysfunction, anhedonia, and changes in immune and autonomic function. In terms of HPA axis function, basal and stress-induced cortisol secretion has been reported to be either increased or reduced. Squirrel monkeys exposed to repeated social separations demonstrate markedly reduced cortisol responses to later separation stress and

increased glucocorticoid feedback sensitivity. Similarly, decreased morning cortisol excretion was recently reported for marmoset monkeys exposed to repeated maternal separation. Another paradigm in nonhuman primates involves the exposure of bonnet macaque mothers with infants to unpredictable conditions with respect to food access for 3 months, resulting in a diminished perception of security and a reduction of maternal care for the infants. When tested as adults, bonnet macaques reared under these conditions demonstrated elevated CSF CRH concentrations, sensitization of the NE system, and behavioral sensitization to fear stimuli. However, their cortisol levels were markedly decreased. Thus, early-life stress appears to result in decreased adrenocortical activity in several nonhuman primate models, closely paralleling findings in PTSD patients.

Although there now are a number of reports of hypocortisolism in nonhuman primates, very few studies on hypocortisolism in rodent models of stress have been published. In one study, social isolation resulted in a reduction of plasma corticosterone levels, both under basal and stress-stimulated conditions. Prenatal exposure to dexamethasone also resulted in decreased HPA axis activity in rat offspring. In rats, a single session of prolonged severe foot shock stress induced enhanced negative feedback sensitivity compared to stress-naïve animals. However, when the rats were stressed again 2 weeks later, no differences in stress responses were observed. Interestingly, one study showed that chronically stressed rats that initially demonstrated lower corticosterone levels developed higher acoustic startle responses and gastrointestinal damage than rats with initially higher levels, suggesting a causal role of relative hypocortisolism for promoting high central stress/fear responses and physical symptoms.

It should be noted that there are numerous reports that adult rats that were subjected to early handling (3–15 min daily) exhibited lower HPA responses to stress and generally better adaptation and health than nonhandled rats. However, it was found that the handling procedure induces increased maternal care after the reunion, probably reflecting a nurturing early environment, whereas the nonhandled rats were more deprived and therefore had relatively increased stress reactivity. This hypothesis was confirmed when directly tested in rats with high and low maternal care.

Potential Mechanisms of Hypocortisolism

As already mentioned, relative hypocortisolism has been described in a multitude of stress-related

conditions that share common symptoms and frequently manifest in comorbidity. Different mechanisms may contribute to decreased cortisol output under various conditions, and different facets of hypocortisolism have been emphasized for different study groups. For example, increased negative feedback inhibition has been emphasized for PTSD, adrenocortical dysfunction has been suggested for FMS, and central origins of hypocortisolism have been suggested for CFS. Clearly, to date, all of the possible contributing mechanisms have not been sufficiently studied in all of the disorders that appear to be related to hypocortisolism. It might well be that there is heterogeneity within diagnostic groups that might reflect different pathways to illness. Future studies should systematically scrutinize each of these disorders in terms of multiple potential mechanisms. Potential mechanisms include (1) reduced biosynthesis or depletion at several levels of the HPA axis (CRH, ACTH, and cortisol); (2) CRH hypersecretion and adaptive downregulation of pituitary CRH receptors, resulting in lower than normal ACTH and cortisol secretion once a stressor stops and CRH secretion returns to normal levels; (3) increased feedback sensitivity of the HPA axis; and (4) morphological changes (i.e., decreased adrenal gland volume). Lack of cortisol effects may also result from relative glucocorticoid resistance of target cells due to receptor changes; decreased availability of free, biologically active cortisol due to alterations in binding proteins; changes in enzyme activity (i.e., 11- β -hydroxysteroid dehydrogenase) that metabolizes glucocorticoid hormones on entry into the cell; and changes in the multidrug resistance pump, which extrudes cortisol but not corticosterone from the target cell.

It should be noted that superimposed factors, such as the nature or timing of the stressor, coping styles, personality, sex, and genetic variations probably contribute to hypocortisolism and might influence the specific mechanisms of its manifestation in relation to stress. For example, the timing of stress during development influences the direction of HPA axis changes in nonhuman primates. Passive-avoidant coping and alexithymic personality appear to be linked to hypocortisolism. Women generally have lower free-cortisol responses to psychosocial stress than men. Basal cortisol levels and HPA axis responses to stress have been shown to be influenced by genetic factors in twin studies. Finally, polymorphisms in genes involved in the stress response, such as the glucocorticoid receptor (GR) gene, have been shown to markedly moderate neuroendocrine responses to stress. In addition to these factors, it has been suggested that hypocortisolism might reflect

different symptom constellations or phases during the course of illness. Taken together, integrative longitudinal research approaches are needed to address the mechanisms of hypocortisolism, together with contributing factors and illness characteristics, in the future.

Effects of Hypocortisolism on Disease Vulnerability

There are several avenues through which the lack of cortisol might lead to characteristic symptoms of pain, fatigue, and anxiety/stress sensitivity. First, glucocorticoids secreted during stress induce gluconeogenesis, mobilize free fatty acids, and reduce the use of amino acids for protein synthesis, thereby increasing the organism's energy supplies. Altered metabolism during stress due to hypocortisolism might lead to exhaustion and fatigue.

Second, glucocorticoids exert inhibitory effects on the secretion of pro-inflammatory cytokines, such as interleukin (IL)-6 and tumor necrosis factor (TNF)- α , during stress and help return these cytokines to baseline levels after stress. These cytokines regulate cellular immunity and mediate pain. Increased or prolonged cytokine activity in the brain leads to impaired cognitive function and mood and anxiety symptoms through the stimulation of CRH-NE systems. Thus, the lack of glucocorticoid effects probably promotes the disinhibition of pro-inflammatory cytokines during stress, resulting in increased vulnerability to developing chronic fatigue, chronic pain, allergies, asthma, and emotional disorders. Interestingly, elevated pro-inflammatory cytokine levels have been reported for PTSD and several functional somatic syndromes, although the findings are inconsistent. Patients with adrenal insufficiency also have elevated levels of pro-inflammatory cytokines, such as IL-6, as well as symptoms of fatigue and pain.

Third, cortisol exerts direct effects on the brain and behavior. Thus, glucocorticoids exert negative feedback effects on the CRH-induced activation of the locus ceruleus NE cells. Relatively decreased cortisol output may have permissive effects toward an increased and sustained activation of the feed-forward cascade between the CRH and NE systems, perhaps in concert with elevated cytokine responses. CRH and NE are implicated in enhanced encoding of traumatic emotional memories, facilitation of fear conditioning, and increased vigilance and arousal, including increased startle responses, leading toward the three symptom clusters of PTSD. Enhanced CRH-NE activation might further stimulate the immune system, promoting fatigue and pain, and

might promote gastrointestinal disturbance. This model suggests that hypocortisolism indeed might occur as a preexisting (genetic or stress-related) risk factor that promotes the development of a spectrum of emotional and somatic disorders. In support of this hypothesis, increased autonomic activity and low cortisol secretion directly after the trauma are significant predictors of the development of PTSD. Low cortisol levels presurgery predict the development of ongoing pain and immune-NE hyperactivation after surgery in FBS patients.

Clinical Implications

If hypocortisolism indeed is causally involved in the development of certain stress-related disorders, reflecting a preexisting risk factor, this has seminal clinical implications. Once normative values are established, hypocortisolism could be measured in healthy subjects to predict the risk of developing PTSD or functional somatic disorders should severe or ongoing stress occur. Consequently, the substitution of hydrocortisone should have preventive effects. In fact, the administration of hydrocortisone during trauma has been shown to effectively prevent PTSD in humans in several studies. In addition, it was recently demonstrated that hydrocortisone treatment, simulating normal circadian cortisol rhythm, is effective in the treatment of PTSD. Randomized controlled clinical trials, furthermore, showed that some (but not all) patients with CFS benefit from hydrocortisone treatment.

In conclusion, given the high prevalence of disorders related to hypocortisolism, the development of studies aiming to describe the mechanisms of hypocortisolism across and within disorders, to scrutinize the effects of hypocortisolism in target cells of the immune system and CNS, and to reverse these effects surely is a promising and exciting area of future research.

Physiological Responses to Hypoglycemia
Effects on Cerebral Function
Causes and Investigations

Glossary

<i>Autonomic reaction</i>	Physiological manifestations of acute activation of the sympathetic (sympathoadrenal) division of the autonomic nervous system, through the autonomic neural stimulation of end organs and secretion of catecholamines.
<i>Awareness of hypoglycemia</i>	The subjective perception of the onset of symptoms generated by a decline in blood glucose.
<i>Cognitive dysfunction</i>	The impairment of intellectual and mental activities as a consequence of interference with cerebral function.
<i>Counter-regulation</i>	The process that promotes the secretion of hormones that oppose the actions of insulin, provoking metabolic changes that elevate blood glucose.
<i>Gluconeogenesis</i>	The production of new glucose from three carbon precursors, principally in the liver and kidney.
<i>Glucose homeostasis</i>	The metabolic maintenance of blood glucose within a narrow range by regulatory mechanisms. The main factors controlling this are the intake of nutrients, the rates of gastric emptying and intestinal absorption, the hepatic production of glucose, and the secretion of insulin and counter-regulatory hormones.
<i>Glycemic threshold</i>	The blood glucose concentration at which a specific event is triggered during the development of hypoglycemia (e.g., onset of symptoms).
<i>Glycogenolysis</i>	The breakdown of hepatic glycogen into glucose, which is released into the circulation.
<i>Neuroglycopenia</i>	The direct effect of glucose deprivation on neurons in the central nervous system.

Hypoglycemia (low blood glucose) is a biochemical abnormality that can be arbitrarily defined by a low blood glucose concentration. In a person with diabetes,

a blood glucose below 3.5 mmol l^{-1} (61 mg dl^{-1}) is considered to represent hypoglycemia; in a nondiabetic person, a blood glucose below 2.2 mmol l^{-1} (38 mg dl^{-1}) is almost always pathological. Hypoglycemia *per se* is not a clinical diagnosis, and a cause for the low blood glucose should be sought.

Physiological Responses to Hypoglycemia

The human brain requires a continuous supply of glucose as its principal source of energy and malfunctions rapidly if deprived of this substrate. To protect the brain and prevent a dangerous fall in blood glucose, multiple counterregulatory mechanisms have evolved to maintain glucose homeostasis. These include the secretion of counterregulatory hormones including glucagon, epinephrine (adrenaline), cortisol, and growth hormone; the centrally activated release of various neurotransmitters; and simultaneous inhibition of endogenous insulin secretion. Hepatic autoregulation can release glucose during profound hypoglycemia. The secretion of pancreatic glucagon occurs independently of the activation of counterregulatory mechanisms within the brain. In contrast, epinephrine is secreted secondary to the stimulation of the sympathetic division of the autonomic nervous system following the activation of autonomic centers within the hypothalamus. The other counterregulatory hormones are released through the activation of the hypothalamic-pituitary-adrenal axis. These hormones promote the breakdown of glycogen to glucose within the liver (hepatic glycogenolysis) and the production of three carbon precursors from proteolysis and glycogenolysis in the skeletal muscle that are used for glucose formation (gluconeogenesis) within the liver and kidney. The oxidation of free fatty acids, produced by lipolysis, provides energy for gluconeogenesis.

Hypoglycemia generates symptoms (1) as a direct consequence of glucose deprivation of neurons in the brain (neuroglycopenia) and (2) secondary to acute autonomic stimulation. Symptoms are idiosyncratic and age-specific, varying considerably among individuals, both in nature and intensity. Common autonomic symptoms are sweating, trembling, pounding heart, hunger, and anxiety; neuroglycopenic symptoms include inability to concentrate, drowsiness, confusion, difficulty with speech, and incoordination. Common nonspecific symptoms include nausea, tiredness, and headache. The recognition of the early onset of the symptoms of hypoglycemia is essential for people

with diabetes who are treated with insulin so that a correction of the low blood glucose can be made.

Symptomatic hypoglycemia is usually associated with the activation of the autonomic nervous system and a rise in plasma catecholamines of similar magnitude to that observed during major vascular events such as acute myocardial infarction and subarachnoid hemorrhage. Hypoglycemia can therefore represent a severe form of stress, which provokes major pathophysiological consequences. Catecholamines provoke hemodynamic changes through their direct effects on the cardiovascular system, causing changes in regional blood flow, and the effects on various

organs induce physiological changes that are identified as autonomic symptoms (Figure 1). This is sometimes described as an autonomic reaction. A transient rise in heart rate is accompanied by an elevation in systolic blood pressure and a decline in diastolic blood pressure, with increased myocardial contractility and cardiac output. Blood flow is increased to the brain, heart, liver, gut, retina, and skeletal muscles, but is decreased to organs such as the kidney and spleen. Hypoglycemia also provokes significant hemostatic and hemorrheological changes (mainly through hormonal action), which can affect the microcirculation.

Figure 1 Autonomic neural pathways involved in the generation of the peripheral physiological manifestations and symptoms during insulin-induced hypoglycemia.

Figure 2 Glycemic thresholds for the secretion of counterregulatory hormones and the onset of physiological, symptomatic, and cognitive changes in response to acute hypoglycemia in nondiabetic adults. Glycemic thresholds are shown in relation to glucose values in arterialized venous blood. Reproduced from Frier, B. M. and Fisher, B. M. (eds.) (1999), *Hypoglycaemia and clinical diabetes*, Chichester, UK: John Wiley. Copyright 1999 John Wiley & Sons Limited. Reproduced with permission.

Effects on Cerebral Function

A progressive decline in blood glucose triggers a hierarchy of events that occur at individual glycemic thresholds (Figure 2). Counterregulation is stimulated when arterial blood glucose falls below 3.8 mmol l^{-1} , and impairment of cognitive function commences below 3.0 mmol l^{-1} . Early changes are subtle, and progressively greater cognitive impairment occurs around 2.6 mmol l^{-1} , with deteriorating performance evident in tests of several cognitive domains. Some of the neuroglycopenic symptoms of hypoglycemia are subjective manifestations of impaired cognitive function. Hypoglycemia also induces noncognitive changes in mood and behavior, including feelings of tense tiredness, unhappiness, fear, despondency, and, in some individuals, anger. Autonomic symptoms commence around 3.0 mmol l^{-1} , and the effects on neurophysiological function (sensory-evoked potentials and electroencephalographic abnormalities) become more prominent as blood glucose falls further. If the condition is untreated, confusion and drowsiness will progress to loss of consciousness and coma. The comatose state may be complicated by convulsions. Significant brain damage is rare and occurs only if the neuroglycopenia is protracted, leading to brain death. Thus, hypoglycemia can vary significantly in severity, ranging from asymptomatic biochemical hypoglycemia to profound coma. In people with insulin-treated

diabetes, severe hypoglycemia is defined by the need of the individual for external assistance for recovery, in which situation acute neuroglycopenia is interfering with the individual's capability for self-treatment. Severity is not determined by the intensity of the symptomatic response or the development of coma.

Glycemic thresholds are not fixed, can vary among individuals, and, in people who have diabetes, can be influenced by recurrent exposure to hypoglycemia. In some people with insulin-treated diabetes, their symptom profile alters with time, the perception of the onset of symptoms becomes diminished, and they may develop a degree of impaired awareness of hypoglycemia. This is a major risk factor for severe hypoglycemia. With the increasing duration of insulin-treated diabetes, deficiencies of counterregulatory hormonal secretion often develop as an acquired defect, and this also increases the risk of severe hypoglycemia. This problem co-segregates with impaired awareness of hypoglycemia. In affected individuals, the glycemic thresholds for the onset of autonomic symptoms and for counterregulatory hormonal secretion are reset at a lower blood glucose than usual, allowing neuroglycopenia to supervene and interfere with the patient's ability to self-treat hypoglycemia. These acquired abnormalities are associated with strict glycemic control (particularly when glycated hemoglobin is within the nondiabetic range) and with repeated

exposure to episodic (antecedent) hypoglycemia, and they occur in other conditions that cause chronic or recurrent hypoglycemia, such as insulin-secreting tumors (e.g., insulinoma). These changes represent an adaptation by the brain to allow it to function during glucose deprivation.

Although total cerebral blood flow is increased during hypoglycemia, the regional changes in blood flow within the brain vary considerably, being increased to frontal areas (including the cerebral cortex) and reduced in posterior regions of the brain. Localized changes in cerebral blood flow may provoke some of the neurological manifestations of hypoglycemia such as transient hemiplegia. However, the rate-limiting factor in protecting the brain against neuroglycopenia is the transport of glucose across the blood–brain barrier. Glucose transporters can be upregulated in response to chronic hypoglycemia, but this process is relatively slow and it takes time (hours to days) for the human brain to adapt and be able to function at low concentrations of blood glucose. Such a modification is essentially maladaptive because the warning symptoms of impending neuroglycopenia are obtunded, reducing the time available to detect the falling blood glucose and increasing the risk of progressing to severe hypoglycemia.

Hypoglycemic coma is associated with the release of excitatory amino acids, including glutamate and aspartate, which activate subtypes of excitatory amino acid receptors including N-methyl-D-aspartate receptors. Membrane depolarization occurs and leads to neuronal necrosis. The brain is affected in a rostro-caudal direction, with the cerebral cortex and hippocampus being most sensitive to neuroglycopenia; the brain stem and spinal cord are much more resistant. In fatal cases of hypoglycemic coma, the neuropathology of the brain is variable, but the laminar necrosis of neurons occurs in the third to fifth layers of the cerebral cortex. Survivors of severe protracted hypoglycemic coma develop cortical and hippocampal atrophy, with ventricular enlargement, often associated with a chronic vegetative state. The cumulative effects of recurrent severe hypoglycemia may cause intellectual impairment in the developing brain of infants and young children, but in adults (principally those with insulin-treated diabetes) the effect on cognitive impairment appears to be modest, with occasional anecdotal exceptions. Progression to severe intellectual impairment and dementia is rare, although a few cases have been described, particularly in patients exposed to chronic neuroglycopenia of long duration, for example in association with an undiagnosed insulin-secreting tumor. Although repeated exposure of people with insulin-treated diabetes to severe hypoglycemia may induce modest cognitive

impairment, this may primarily be caused by other co-existing morbidities, such as hypertension, chronic hyperglycemia (poor glycemic control), and cerebrovascular disease, and underlies the concept of a diabetic encephalopathy.

Causes and Investigations

Multiple causes of hypoglycemia are recognized in humans, but most are rare. In the nondiabetic population, hypoglycemia is most commonly associated with excessive alcohol consumption. However, by far the most common cause is iatrogenic, resulting from the inadvertent use of insulin or drugs that promote insulin secretion (mostly sulfonylureas), which are used for the treatment of diabetes. Occasionally, hypoglycemia is the presenting feature of an illness or occurs as an important epiphenomenon, and it is then considered to be spontaneous. The classification of hypoglycemia can be based on etiology (see [Table 1](#)) or, alternatively, on whether insulin is detectable. Subdivision into “fasting” and “reactive” types of hypoglycemia is no longer used. The spectrum of causes of hypoglycemia varies between hospital and community practice. In hospitalized patients, hypoglycemia is associated with diabetic therapies, chronic renal failure, infections, liver disease, shock, pregnancy, neoplasia, and burns. In the community, excessive alcohol consumption and therapies for treating diabetes predominate as the main causes.

Hypoglycemia is usually episodic, but the symptoms that are commonly experienced with acute insulin-induced hypoglycemia may be absent in people who present with spontaneous hypoglycemia. A low blood glucose level should be suspected in people who present as an acute medical emergency with collapse, altered consciousness, convulsions, abnormal neurological findings, or confusion. A suspicion of underlying hypoglycemia should be considered even when an obvious cause of cerebral abnormality is apparent, such as hemiplegic stroke, alcoholic intoxication, or cerebral malaria. An accurate and reliable history may be difficult to obtain from the patient, and an objective account from witnesses may be valuable. Where subacute neuroglycopenia presents with deteriorating cognitive function over months or years, psychiatric features may be prominent, and such patients may have been referred to a neurologist or psychiatrist for investigation of funny turns, feeling faint, odd behavior, paresthesiae, or convulsions. In some cases, the only indication that hypoglycemia is responsible is the finding of a low blood glucose level on routine biochemical screening.

Tumor-induced hypoglycemia may occur as a pre-terminal feature of an advanced malignancy,

Table 1 Causes of hypoglycemia in adults

Type	Causes
Toxic hypoglycemia	Therapeutic hypoglycemic agents: insulin, sulfonylureas Alcohol Drugs, e.g. quinine, salicylates, propranolol, pentamidine Poisons, e.g. certain types of mushroom
Pancreatic	Insulinoma: benign, malignant, multiple and microadenomatosis Islet hyperplasia with functional hyperinsulinism
Extrapancreatic neoplasms	Mesenchymal tumors Hemangiopericytoma Primary hepatic carcinoma Various other tumors
Liver and kidney disease	Hepatocellular disease; cirrhosis Advanced renal failure Congestive cardiac failure
Endocrine disease	Pluriglandular syndrome Pituitary insufficiency Adrenocortical insufficiency Selective hypothalamic insufficiency
Autoimmune hypoglycemia	Autoimmune insulin syndrome Anti-insulin receptor antibodies
Inborn errors of metabolism	Adult glycogenolysis (liver glycogen disease) Hereditary fructose intolerance
Miscellaneous	Sepsis; burns Prolonged starvation; anorexia nervosa Dialysis Excessive, strenuous exercise Diseases of the nervous system Falciparum malaria

particularly in patients with extensive hepatic metastases and also with some very large tumors such as fibrosarcoma. Some tumors secrete substances with insulin-like activity; malignancies involving the liver disrupt hepatic gluconeogenesis and the maintenance of glucose homeostasis. Insulinomas are pancreatic islet cell tumors that secrete insulin and usually cause recurrent fasting hypoglycemia. They are rare (one to two cases per million population per year) but are one of the commonest causes of spontaneous hypoglycemia in nondiabetic individuals. Symptoms may occur before meals or during exercise and are relieved by the consumption of food or a glucose drink. The tumors are usually small (0.5–5 mm in diameter) and may occur in any part of the pancreas. Approximately 10% are malignant.

A firm diagnosis of hypoglycemia is usually based on Whipple's triad:

- Symptoms are associated with fasting or exercise.
- Symptoms are relieved by glucose.
- Low blood glucose is demonstrated by biochemical analysis.

In the investigation of suspected hypoglycemia, low blood glucose should be confirmed by laboratory analysis of venous or capillary blood glucose. Hypoglycemia is often associated with inappropriately elevated plasma insulin concentrations. Blood should be collected during the emergency presentation, and the plasma frozen and stored, both for immediate confirmation of hypoglycemia and for additional analyses (e.g., for hormones, alcohol, and drugs), which may identify a cause. This can avoid subsequent unnecessary investigations and is of forensic and medical-legal importance in cases of attempted suicide or deliberate poisoning.

The nature and timing of blood samples for the measurement of glucose are important in the evaluation of the causes of hypoglycemia. The possible development of a large arteriovenous difference after glucose absorption precludes the use of glucose tolerance tests that require an oral glucose load because the arterial plasma glucose concentration is 15% higher than that estimated from whole venous blood. Provocative tests for investigating suspected hypoglycemia include prolonged fasting with or without exercise and the infusion of intravenous insulin to induce hypoglycemia to see whether C-peptide (an index of endogenous insulin secretion) is suppressed. Plasma concentrations of insulin, C-peptide, pro-insulin, and other hormones such as insulin-like growth factor (IGF)-1 may also be measured during confirmed hypoglycemia. Characteristic patterns of plasma glucose and insulin are associated with different causes of hypoglycemia, and a diagnosis of endogenous hyperinsulinism depends on evidence of inappropriate insulin and/or C-peptide secretion in the presence of hypoglycemia. With an insulinoma, a mesenchymal tumor, and a sulfonylurea overdose, the fasting plasma insulin is usually inappropriately high for the prevailing blood glucose and endogenous insulin secretion is not suppressed. This can be demonstrated by elevated plasma C-peptide during insulin-induced hypoglycemia. Factitious hypoglycemia is characteristically associated with elevated plasma insulin and absent plasma C-peptide in nondiabetic individuals, indicating that an overdose of exogenous insulin has been administered.

True reactive hypoglycemia may occur in patients who have had previous gastric surgery or who have gastrointestinal motility disorders. However, some individuals describe symptoms suggestive of, but without biochemical evidence of, hypoglycemia that occur 1–2 h after food. This is called the postprandial syndrome, and such patients should be evaluated with ambulatory blood glucose measurements or by serial measurements of plasma glucose and insulin

after a standard mixed meal, plus recording of symptoms and dietetic assessment.

The emergency treatment of acute hypoglycemia should not be withheld to await a confirmatory biochemical diagnosis. In diabetic patients, self-treatment of mild hypoglycemia requires the ingestion of a glucose drink or food. More severe hypoglycemia can be treated with intravenous glucose or intramuscular glucagon. In noniatrogenic causes of hypoglycemia, treatment depends on the specific diagnosis. Tumor-induced hypoglycemia may require prolonged therapy if surgical resection is not possible or the tumor cannot be located. Treatment with diet (regular intake of oral carbohydrate) and drugs that inhibit insulin secretion (e.g., diazoxide), thiazide diuretics, and somatostatin analogs (e.g., octreotide) may be beneficial. Patients with true reactive hypoglycemia usually respond to dietary measures such as the exclusion of highly refined sugars and the consumption of frequent regular meals that are high in fiber content; the α -glucosidase inhibitor acarbose may be beneficial.

Introduction

Neuroendocrine Regulation in Hypotension and Hypovolemia
Septic Shock

Glossary

<i>Aldosterone</i>	A mineralocorticoid hormone produced by the zona glomerulosa of the adrenal cortex and a key regulator of potassium balance where it induces sodium and water retention.
<i>Angiotensin II</i>	An octapeptide which acts to increase peripheral arterial resistance, raising

Atrial natriuretic peptide (ANP)

Circulatory shock

Cytokines

Hypotension

Hypovolemia

Multiple organ dysfunction syndrome

blood pressure, and stimulates aldosterone biosynthesis.

A polypeptide hormone mainly synthesized in the cardiac atrium, released following atrial dilatation or increased intravascular volume, and involved in natriuresis and the regulation of blood pressure and volume homeostasis.

A generalized inadequacy of blood flow throughout the body, to the extent that the tissues are damaged because of too little flow, especially too little delivery of oxygen to tissue cells.

Polypeptide cell regulators, mainly produced by cells of the immune system, which all affect in some way the function of the immune system and have the ability to act as communication signals.

A systolic blood pressure of <90 mmHg or a reduction of ≥ 40 mmHg from baseline.

An abnormal decrease in blood (plasma) volume.

The presence of altered organ dysfunction in an acutely ill patient such that homeostasis cannot be maintained without intervention.

<i>Renin</i>	A glycoprotein hormone and proteolytic enzyme produced by the juxtaglomerular cells of the kidney in response to hypovolemia and hypotension and it cleaves its substrate angiotensinogen into angiotensin I.
<i>Sepsis</i>	The systemic response to infection.
<i>Septic shock</i>	Sepsis-induced hypotension, despite adequate fluid resuscitation along with the presence of perfusion abnormalities which may include, but are not limited to, lactic acidosis, oliguria, or an acute alteration in mental status.
<i>Sympathoadrenal system</i>	An anatomical and physiological unit of the adrenal medulla and the sympathetic nervous system.
<i>Vasopressin</i>	A polypeptide hormone produced in the hypothalamus and stored in the posterior pituitary from which it is secreted upon osmotic and hemodynamic stimuli. Once released, it induces vasoconstriction and promotes free water clearance. Also known as antidiuretic hormone.

present. In severe shock, the perfusion of heart and brain is inadequate with severe acidosis and an altered mental state. Finally, the cardiac output diminishes, which further compromises the blood pressure, and respiratory failure will develop.

Circulatory shock is characterized by a failure to maintain adequate tissue perfusion and an impaired oxygen delivery which will ultimately lead to anaerobic metabolism and adenosine triphosphate (ATP) depletion and mitochondrial dysfunction. In general, three stages of shock can be distinguished: early (non-progressive), progressive, and irreversible. The most frequent causes of shock can be divided in cardiogenic, distributive (such as sepsis or anaphylaxis), hypovolemic, and obstructive shock ([Table 1](#)).

Septic shock is more life threatening than hypovolemic or cardiogenic shock, because it is always accompanied by microcirculatory dysfunction and cellular membrane injury, which can lead to multiple organ dysfunctions. This severe stress state involves cardiac dysfunction, acute renal failure, adult respiratory distress syndrome, and hepatic failure.

Introduction

The survival of multicellular organisms is exquisitely dependent on the continuous provision of all body cells with fluid, oxygen, minerals, nutrients, and the uninterrupted elimination of metabolic waste products in order to provide the cells and tissues with the essential circumstances necessary for life. To ensure these vital conditions an intact vascular and microvascular blood flow is a primary prerequisite. Any serious failure of the circulatory system to maintain the cellular perfusion and a fluid homeostasis causes a syndrome of clinical symptoms due to abnormal cellular metabolism, membrane dysfunction, and cell death in tissues and organs throughout the body, eventually ending up in death of the whole organism.

The main symptoms of circulatory failure include hypotension and tachycardia and the patient may show profuse perspiration, the extremities are cool and mottled, and peripheral pulses are weak or impalpable. Due to inadequate perfusion of the brain, a shock state can be demonstrated by restlessness, anxiety, confusion, somnolence, and unconsciousness up to deep coma. In cases of mild shock, there is a decreased perfusion of nonvital organs, such as skin, adipose tissue, skeletal muscle, and bones. The mental state is unimpaired; the urine output may be slightly decreased. In moderate shock, the perfusion of liver, gastrointestinal tract, and kidneys is decreased, but that of the heart and brain is still intact. Urine production is diminished and metabolic acidosis is

Table 1 Classification and etiology of circulatory shock

Hypovolemic shock
Decreased preload and subsequently decreased cardiac output
Hemorrhage (external or internal)
Fluid loss (diarrhea, vomiting, heat stroke, inadequate repletion of insensible losses, burns, and "third spacing" (which can occur in intestinal obstruction, pancreatitis, and cirrhosis)
Cardiogenic shock
Pump failure (infarction, cardiomyopathy, myocarditis)
Arrhythmias (both atrial and ventricular)
Mechanical abnormalities (acute valvular insufficiency, rupture ventricular wall)
Distributive (vasodilatory) shock
Severe decrease in systemic vascular resistance, often associated with an increased cardiac output
Septic shock
Activation of the systemic inflammatory response (pancreatitis, burns, or multiple traumatic injuries)
Toxic shock syndrome
Anaphylaxis and anaphylactoid reactions
Addisonian crisis
Myxedema coma
Neurogenic shock
Post-cardiopulmonary bypass
Obstructive shock
Massive pulmonary embolism
Tension pneumothorax
Severe constrictive pericarditis
Pericardial tamponade
Severe pulmonary hypertension producing Eisenmenger's physiology

Neuroendocrine Regulation in Hypotension and Hypovolemia

Because hypotension and/or hypovolemia compromise the distribution of essential nutrients to body tissue, they represent a threat to homeostasis. Homeostatic systems such as blood and tissue oxygen, acid-base status, and body temperature must be maintained within narrow ranges. Accordingly, hypovolemia- and/or hypotension-induced hormonal responses are part of the well-orchestrated defense mechanisms of the three major central systems of the individual: the nervous, endocrine, and immune system. Acute changes in the hormonal functions are primarily adaptive and provide optimal conditions of the organism for the fight, including optimal intravascular volume and perfusion pressure. Under physiological conditions the acute reaction of the body to these challenges is twofold, turning on defense mechanisms that initiate a complex adaptive pathway (adaptive phase), and then shutting off this response when the threat is past (recovery phase). However, there are limits to the ability of the hormonal system to compensate adequately when the inappropriate hormonal response can contribute to the breakdown of the body tissue (catabolic phase). Hormonal changes during or following hypotension and/or hypovolemia are summarized in [Table 2](#). Salt and water balance is largely determined by factors regulating fluid and electrolyte intake and, more importantly, the ability of the kidney to regulate sodium and water excretion. Vasopressin, the renin-angiotensin-aldosterone (RAA) axis and the sympatho-adrenal system are the key players in the regulation of volume and water during stress ([Figure 1](#)).

Critical illness such as shock is characterized by striking alterations in the hypothalamic-anterior-pituitary-peripheral hormone axes, the severity of which is associated with a high risk of morbidity and mortality. There appears to be a biphasic neuroendocrine response to critical illness. The acute phase is characterized by an actively secreting pituitary, but most peripheral hormones are decreased, partly due to the development of target-organ resistance. This is considered to be beneficial, at least for short-term survival. In prolonged illness, uniform (hypothalamic) suppression of the neuroendocrine axes contributes to low levels of the target-organ hormones. These alterations are considered to be maladaptive and contribute to the catabolism and wasting.

Hypothalamo-Posterior Pituitary System

Vasopressin is a peptide hormone that is synthesized in the hypothalamic nuclei and transported to the posterior pituitary where it is stored. It is released

into the circulation upon stimulation by increased plasma osmolality or as a baroreflex response to decreases in blood volume or blood pressure. Vasopressin exerts antidiuretic, hemostatic, and vasoconstrictive effects via stimulation of V₁- and V₂-receptors. Furthermore, vasopressin serves as a key secretagogue in the body's complex endocrinologic orchestra ([Figure 1](#)). The physiological effect of vasopressin is to promote free water clearance by altering the permeability of the renal collecting duct to water. This effect is mediated by renal V₂-receptors that are coupled to adenylyl cyclase and the generation of cyclic adenosine monophosphate (cAMP). Vasopressin is also capable of causing vasoconstriction and increasing blood pressure. In fact, vasopressin is a more potent vasoconstrictor than norepinephrine and is capable of

Figure 1 Neuroendocrine regulation of shock and hypotension. Thick lines represent positive feedback mechanisms. Thin lines represent less pronounced positive feedback regulation. increasing systemic vascular resistance in doses less than those required to produce antidiuresis. Conversely, vasopressin is a relatively weak pressor agent because it resets the cardiac baroreflex to a lower pressure. These actions are mediated via V_1 -receptors which are coupled to phospholipase C and increased intracellular Ca^{2+} concentration. Aside from the corticotropin-releasing hormone (CRH), vasopressin is known to be the most potent stimulator of adrenocorticotrophic hormone (ACTH) and, consequently, cortisol release. Additionally, vasopressin exerts stimulatory effects on prolactin and endothelin-1 release, and it modulates atrial natriuretic peptide (ANP) and angiotensin II secretion.

Increased vasopressin release is, therefore, a key part of the hypotension- and/or hypovolemia-induced neuroendocrine stress adaptation. Low plasma vasopressin concentration during stress is a sign of the inappropriate autonomic adaptation which has been described in patients with septic or hypovolemic shock. However, it is unclear if this relative vasopressin deficiency has clinical relevance or therapeutic consequences.

Renin-Angiotensin-Aldosterone System

The RAA system plays a pivotal role in the control of cardiovascular homeostasis (**Figure 1**). Renin is a glycoprotein hormone produced by the renal

juxtaglomerular cells in response to hypovolemia and hypotension, but is not a vasoactive substance. Its primary action is to cleave angiotensinogen into the decapeptide, angiotensin I. In the pulmonary circulation, angiotensin-converting enzyme (ACE) removes two more amino acids from angiotensin I to produce angiotensin II, which is the active hormone with a direct strong vasoconstrictor effect (40 times more potent than norepinephrine) and an effect on the adrenal cortex to stimulate aldosterone production. Aldosterone is the key regulator of the potassium balance and induces sodium and water retention. The appropriate response of the RAA axis to hypotension and hypovolemia is renin release, which, via angiotensin II, induces aldosterone secretion by the adrenal cortex, resulting in hyperreninemic hyperaldosteronism, which is a state of secondary hyperaldosteronism often caused by depletion of extracellular fluid and reflected by metabolic alkalosis and hypokalemia. Stress-induced ACTH and vasopressin release also induces aldosterone secretion independently of volume status. An elevated plasma-renin concentration accompanied by inappropriately low aldosterone level is present in some seriously ill patients with hypovolemia and hypotension, and is a sign of the insufficient adaptation of the RAA axis (hyperreninemic hypoaldosteronism, a transient and reversible syndrome characterized by a dissociation of

plasma renin activity and aldosterone production (20–30% of critically ill patients) possibly due to a transient diffuse impairment of the zona glomerulosa of the kidney. Activation of the RAA system occurs during any type of pump failure or shock.

The family of natriuretic peptides consists of ANP, brain (B type) natriuretic peptide (BNP) and C-type natriuretic peptide. ANP is a 28-amino acid polypeptide hormone synthesized in the heart and released into the circulation in response to stretch of the heart chambers, fluid loading, and congestive heart failure. ANP works to oppose the function of the RAA axis via inhibiting the secretion and effects of renin, the effects of angiotensin II, and the adrenal secretion of aldosterone (Figure 1). ANP acts on the kidney to increase sodium excretion and glomerular filtration rate to antagonize renal vasoconstriction. In the cardiovascular system, ANP antagonizes vasoconstriction and shifts fluid from the intravascular to the interstitial compartment. The diuretic and blood pressure lowering effect of ANP may be partially due to adrenomedullin.

BNP and N-terminal pro-brain natriuretic peptide (NTproBNP) are mainly produced in the human ventricle and are cleaved from their inactive precursor proBNP. Both ANP and BNP levels are elevated in a variety of conditions in the critically ill, such as sepsis, trauma, and shock and have prognostic value.

Sympatho-Adrenal System

The sympatho-adrenal response to severe stress is marked, rapid, and transient and plays an important role in the early metabolic changes during the acute phase of a stress response (Figure 1). Epinephrine is secreted from the adrenal medulla in direct response to increased sympathetic tone; however, the majority of the circulating norepinephrine is released from the sympathetic nerve endings. Both catecholamines support blood pressure, heart rate, myocardial contractility, cardiac output, respiration, and bronchial tone. Epinephrine is an important catabolic hormone, inducing lipolysis, glycogenolysis, and gluconeogenesis, and stimulates glucagon release and inhibits insulin release. A high level of plasma catecholamines has been found during the acute phase of a stress response, but the measurements of plasma catecholamine concentrations have limited value as an index of the sympathetic nervous system activity because of their extremely short half-life.

Hypothalamo-Pituitary-Adrenal Axis

The hypothalamic-pituitary-adrenal (HPA) axis does not follow a simple activation response but rather demonstrates a biphasic process during hypotension

and/or hypovolemia. There is a prompt, dramatic, and sustained increase in both cortisol and ACTH concentration in blood. This activation is accompanied by a loss of circadian rhythm, ACTH pulsatility, and CRH sensitivity of the pituitary. During the second catabolic phase the high plasma cortisol level is accompanied by paradoxically low ACTH levels. Vasoactive peptides such as vasopressin, endothelin, ANP, or calcitonin gene-related peptide (CGRP) are implicated in the adrenal activation in this stage. The degree of cortisol elevation correlates with the degree of homeostatic disturbances.

Neuropeptides

In addition to these classical stress hormones, several other hormones are augmented in response to hypotension and/or hypovolemia. There is no doubt that prolactin and growth hormone (GH) are released during this stress response but the biological meaning is much less clear. However, there are experimental observations that neuropeptides may play a causal role in the hypotension and/or hypovolemia-induced cardiovascular responses. There is now appreciable evidence that one such group of neuropeptides, the endogenous opioids, exert a major influence on cardiovascular responses as a counter-stressor system. In canine hemorrhagic shock models, administration of the opioid antagonist naloxone significantly improved mean arterial pressure without change in heart rate and total peripheral resistance; increased cardiac contractility and cardiac output; and reduced mortality. In patients with hemorrhagic shock, infusion of opiate antagonist resulted in improvement in hemodynamic status via a significant fall in heart rate together with improvement in stroke volume without reduction in cardiac output, and reduction in vasopressor requirements. Based on these observations, it has been suggested that although hypovolemic shock is best treated in the human by volume repletion, in an emergency situation, an opioid antagonist might stabilize the patient until the institution of conventional therapy. In addition to endogenous opiates, the endogenous release of the potent vasoconstrictor neuropeptide Y (NPY) is increased in hypovolemic shock. NPY co-exists and is co-released with norepinephrine, and causes direct vasoconstriction and potentiates norepinephrine-induced vasoconstriction in a complex manner. NPY plays a relatively minor role in the minute-to-minute maintenance of cardiovascular homeostasis; its role being one of a second line of defense that comes into play in situations of greater or more prolonged stress. However, the role of CGRP, the most potent vasodilator and hypotensive agent yet tested, has been also suggested as a

causal factor in hypotension-induced stress response. Plasma CGRP levels are related to hemodynamic changes and there is a correlation between the initial CGRP plasma level and the severity of the shock. It is possible that neuropeptides, especially endogenous opiates, represent a physiological buffer of the cardiovascular response to stress, namely as a major counter-stressor system exerting significant influence on cardiovascular responses to both physiological and pathophysiological stresses in animals and humans.

Septic Shock

Septic shock is the most common cause of death in intensive care units. The terms sepsis, severe sepsis, and septic shock are used to identify the continuum of the clinical response to infection. However, the definition of sepsis appears to be very complicated because of the nonhomogenous nature of the patient population studied and the underlying conditions related to sepsis. Septic shock is hypoperfusion with organ dysfunction in a septic patient. Sepsis represents a severe threat to homeostasis and it is related to a systemic inflammatory host response to an inciting event. In general terms, sepsis is a severe stress stimulus which disturbs the milieu interne and induces homeostatic responses specific to the stimulus and generalized responses when the disturbances are severe. Regulation of fluid and volume status is of critical importance to survival. Multiple mechanisms exist to maintain normovolemia and adequate blood pressure in sepsis, and when they fail septic shock arises. Septic shock is often characterized by massive systemic vasodilatation with low vascular resistance, and increased cardiac output. The relative lack of effective pharmacologic interventions highlights the complex pathophysiologic events involved in sepsis. In this paragraph we focus on the pathogenesis, and neuroendocrine-immune interactions (Figure 2).

Pathogenesis

The clinical manifestations of septic shock are the result of an excessive host response to an (usually bacterial) infection. Although host defense mechanisms are usually beneficial and designed to localize and neutralize invading micro-organisms, remove dead and damaged cells, and repair tissue damage, excessive activation may be detrimental. The inflammatory response to infection or injury is a highly conserved and regulated reaction of the organism. Immediately, the organism produces several soluble and lipid pro-inflammatory molecules that activate cellular defenses and then produces similar anti-inflammatory molecules to attenuate and halt the pro-inflammatory

Figure 2 Bidirectional interactions between the neuroendocrine and immune systems during critical illness.

response. The complex interaction of these stress mediators can be seen as a cascade. The initial inflammatory response is kept in check by downregulating production and counteracting the effects of cytokines already produced. These mediators initiate overlapping processes that influence the endothelium, cardiovascular, hemodynamic, and coagulation systems directly. The release of many of these vasoregulators is often local, as part of the total septic-response picture. The overproduction of nitric oxide (NO), a potent vasodilator, has been held responsible for the hemodynamic and metabolic consequences of sepsis and endotoxemia. High levels of nitrite and nitrate, the stable end-products of NO metabolism, are found in patients with septic shock and these levels correlate with vasodilatation and the degree of shock.

The duration of illness also may alter the mix of mediators, leading to a state of metabolic disorders in which the body has no control over its own inflammatory response. If the balance cannot be established and homeostasis is not restored, a massive pro-inflammatory reaction (sepsis inflammatory response syndrome; SIRS) or a compensatory anti-inflammatory reaction (compensatory anti-inflammatory response syndrome, CARS) will ensue.

Bone and colleagues have proposed five stages in the development of septic shock and ultimately multiple organ dysfunction:

1. The local reaction at the site of injury or infection: the initial response is to induce a pro-inflammatory state in which mediators (TNF, IL-1, IL-6, interferon- γ , platelet-activating factor) have multiple overlapping effects designed to limit new damage and to ameliorate whatever damage has already occurred. They destroy damaged tissue, promote the growth of new tissue, and combat pathogenic organisms. A compensatory anti-inflammatory response soon ensures that the effects of these pro-inflammatory mediators do not become destructive. IL-4, IL-10, IL-11, IL-13, soluble TNF receptors, IL-1 receptor antagonists, and others work to diminish monocytic major histocompatibility complex class II expression, impair antigen presenting activity, and reduce the ability of cells to produce inflammatory cytokines. Local levels of these mediators can be much higher than are later found systemically.
2. The initial systemic response: if the original insult is severe enough, first pro-inflammatory and later anti-inflammatory mediators will appear in the systemic circulation. The pro-inflammatory mediators help recruit neutrophils, T cells and B cells, platelets, and coagulation factors to the site of injury or infection. Few significant clinical signs are produced.
3. Massive systemic inflammation: the loss of regulation of the pro-inflammatory response results in a massive reaction manifested as the systemic inflammatory response with (a) progressive endothelial dysfunction, (b) platelet sludging blocking the microcirculation, (c) activation of the coagulation system and (d) profound vasodilatation, fluid transition, and maldistribution of blood flow may result in severe shock.
4. Excessive immunosuppression: this 'immune paralysis' or 'compensatory anti-inflammatory response syndrome' is a result of an inappropriate anti-inflammatory reaction.
5. Immunologic dissonance: this is the final stage of MODS, an inappropriate, out-of-balance response of the immunomodulatory system. Sometimes, monocyte deactivation has been shown.

Basic and clinical science continues to reveal the molecular picture for the etiology and pathophysiology of sepsis, however, sepsis continues to puzzle and challenge physicians. Recent discoveries have shown that not only microbial products but also endogenous molecules can trigger Toll-like receptors (TLR),

which are held responsible for the stimulation of widespread inflammation. TLR-4, the endotoxin receptor, is constitutively suppressed and the first step in sepsis could be the release of TLR-4 from suppression.

Neuro-Immuno-Endocrine Interactions

The endocrine and immune systems are interrelated via a bidirectional network through which hormones and neuropeptides affect immune function and, in turn, immune responses are reflected in neuroendocrine changes (Figure 2). Apparently, there is constant interaction between neuroendocrine and internal immunoregulatory mechanisms that assures the fine tuning of both the neuroendocrine and the immune system so that both are able to preserve homeostasis during severe and life-threatening illnesses. Evidence shows that inflammatory cytokines are produced in the brain and endocrine glands and that these organs have cytokine receptors. This suggests that paracrine mechanisms mediated by locally produced cytokines play certain roles in causing endocrine changes in inflammation or sepsis. Similarly, various neuropeptides, including GH and PRL, are produced in immunocompetent cells and neuropeptide receptors are present on these cells.

Many cytokines, such as IL-1 and TNF, can activate the HPA axis, when given by systemic routes. These cytokines seem to act through the hypothalamus via release of CRH, which is the most important regulator of ACTH. IL-1, IL-2, IL-6, and TNF act directly on the adrenal cortex to enhance biosynthesis of glucocorticoids, possibly contributing to the persisting hypercortisolism, present in critical illness. Injection of bacterial lipopolysaccharide (LPS) into healthy volunteers increases plasma TNF within 90 min followed by increases of plasma ACTH and cortisol levels. Plasma IL-6 also increases 2–3 h after LPS injection, but IL-1 and IFN- γ remain unchanged. IL-6, synthesized through increases of IL-1 and TNF plays a pivotal role in activating the HPA axis. Interestingly, IL-6 suppresses IL-1 production indicating a negative feedback regulation within the cytokine cascades. Cytokines are also produced locally in a variety of tissues, including in the brain. Both IL-1 and IL-6 are involved in activation of the HPA-axis. Various stimuli, for example LPS, lead to the production of cytokines in the anterior pituitary gland, acting through a paracrine or autocrine mechanism to modulate ACTH secretion and to regulate growth of pituitary cells. Cytokines can also be produced in the adrenocortical or medullary cells, with a modulating function in steroid hormone production.

Recent studies have led to the discovery of a mediator that acts as an endogenous counter-regulator of glucocorticoid action within the immune system: macrophage migration inhibitory factor (MIF) produced by the anterior pituitary gland, macrophages and T cells in response to inflammatory stimuli and upon incubation with low concentrations of glucocorticoids. Once secreted, MIF overrides the anti-inflammatory and immunosuppressive effects of steroids on macrophage and T cell cytokine production. Patients with sepsis show elevated MIF levels, which are correlated with poor prognosis. Anti-MIF antibodies protect animals from septic shock.

In conclusion, it appears that the acute response of the HPA axis is mediated by cytokines in inflammatory foci. Since cytokine levels in the brain or endocrine organs under unstimulated conditions are very low, the action of cytokines locally produced by LPS requires a certain latent period. Therefore, the paracrine mechanisms may become significant under prolonged stimulation by infectious agents. Metabolic alterations induced by TNF are considered to be dependant on tissue TNF levels, but not on systemic levels. This suggests the importance of locally produced cytokines. As a result of the activation of the HPA axis, glucocorticoids are finally produced and act on the immune system to inhibit the overshoot of cytokine production and to enhance the defense mechanism of the organism. Thus, there exists a feedback mechanism over the immune and endocrine systems; glucocorticoids inhibit cytokine-induced CRH release and also production of certain cytokines in endocrine organs. Another feedback mechanism may exist in cytokine cascades too. Both IL-1 and IL-1 receptor antagonist are produced by the same cells, probably with a different time course, to modulate overstimulation by IL-1. Complex interactions seem to exist also among inflammatory cytokines. These feedback mechanisms are involved in maintaining homeostasis in inflammatory processes and sepsis.

Sepsis may not only be attributable to hyperactivation of the immune system (uncontrolled hyperinflammation) but systemic anti-inflammatory responses might dominate the body's stress response. The immune system may be severely compromised and unable to eradicate pathogens. Future therapy may be directed at enhancing or inhibiting the patient's immune response.

Target Sequelae of Corticosteroid Responses to Stress

Glossary

<i>Adrenocorticotrophic hormone (ACTH)</i>	A proopiomelanocortin-derived peptide of 39 amino acids that is released from the corticotroph and acts on MC-3 receptors on adrenocortical cells to stimulate the synthesis and secretion of adrenal corticosteroids.
<i>Arginine vasopressin (AVP)</i>	A peptide that, in addition to its behavioral and antidiuretic roles, potentiates the action of corticotropin-releasing factor to cause ACTH secretion from the corticotroph.
<i>Corticotropin releasing hormone (CRH)</i>	A 41-amino-acid peptide that acts centrally as a neurotransmitter and releasing factor for ACTH.
<i>Corticosterone (B)</i>	The major corticosteroid synthesized and secreted by rat adrenals; also called Kendall's compound B.
<i>Cortisol (F)</i>	The major corticosteroid synthesized and secreted by human adrenals; also called Kendall's compound.
<i>Glucocorticoid receptor (GR)</i>	A receptor found in cells throughout the body that mediates most of the systemic effects of corticosteroids secreted by the adrenal.
<i>Heterotypic stress</i>	The application of a novel stimulus to animals that have been previously or chronically stimulated by another stressor.
<i>Homotypic stress</i>	The reapplication of the same stressor that has been applied to animals previously.
<i>Paraventricular nucleus (PVN)</i>	The hypothalamic site of CRH and AVP neurons, which subserve both neuroendocrine and autonomic functions.
<i>Proopiomelanocortin (POMC)</i>	The 13-kDa precursor protein of ACTH that is synthesized in the anterior pituitary corticotrophs in response to CRH.

The hypothalamic-pituitary-adrenal (HPA) axis, which ultimately controls the secretion of glucocorticoids from the adrenal cortex, is simply one arm of a central CRH system that appears to be responsible for coordinated behavioral, neuroendocrine, autonomic, and immune responses to alterations in homeostasis. There are marked circadian rhythms in the HPA axis, well integrated with other circadian activity to optimize the daily release of CRH and AVP, and its primary function is to stimulate steroidogenesis by the adrenal cortex. In addition, the HPA axis is responsive to stimuli (stressors) that threaten homeostasis, either psychologically or physically. Responses to acute stressors are essential for life, and they turn on and off rapidly. Chronic stressors appear to change the response characteristics in the HPA axis, possibly through recruiting central neural pathways that normally contribute in only a minor fashion to the acute stress response. During chronic stress, both the CRH- and the glucocorticoid-regulatory components of the HPA axis serve to inhibit activity in other, energy-expending hormonal systems of the body, thus conserving energy stores for immediate use.

The Hypothalamic-Pituitary-Adrenal Axis Is One Neuroendocrine Arm of the Central Corticotropin Releasing Hormone Stress System

CRH in the PVN is the essential driver of the anterior pituitary corticotroph, causing the synthesis and secretion of ACTH, which then activates adrenocortical synthesis and the secretion of the corticosteroids: cortisol (F) in humans and corticosterone (B) in rats. ACTH appears to be a slave to hypothalamic release of CRH and AVP, and its primary function is to stimulate steroidogenesis by the adrenal cortex. Both F and B have important effects on central CRH synthesis, behavior, the immune system, and energy balance.

Neuroendocrine Corticotropin Releasing Hormone Neurons

CRH neurons, primarily in the medial parvocellular portion of the PVN, are known as neuroendocrine neurons. Their axons end at the hypothalamic median eminence, and CRH secreted from these diffuses into the hypophyseal-portal blood supply to excite, through its action on CRH receptor 1 (CRH-R1), the synthesis of POMC and secretion of ACTH into the general circulation. ACTH secreted from the pituitary

appears to have the single peripheral function of exciting adrenocortical MC-3 receptors to cause the synthesis and secretion of aldosterone from the zona glomerulosa and F (in humans) or B (in rats), or combinations of the two in other species from the zona fasciculata. The neuroendocrine CRH-synthesizing neurons in PVN also cosynthesize and secrete AVP, which greatly potentiates the effect of CRH on corticotroph ACTH secretion. The amount of AVP synthesized varies with the state of the organism. After adrenalectomy and the removal of F or B negative feedback or after some chronic stressors, AVP synthesis increases markedly in CRH cells. The increase in CRH neuronal AVP allows persistent responsiveness in the HPA axis under conditions when a high corticosteroid feedback signal would otherwise damp the system.

Autonomic Corticotropin Releasing Hormone Neurons in the Paraventricular Nucleus

There are also CRH cells in the dorsal, lateral, and medial parvocellular regions of PVN that innervate the dorsal vagal complex and interomedial lateral portions of the spinal cord, suggesting that they affect neural outflow to the peripheral autonomic nervous system.

Other Corticotropin Releasing Hormone Neuronal Groups

Within the brain, there are clusters of other CRH-synthesizing neurons, in addition to those in the PVN, that also appear to play key roles in behavior, autonomic activity, and energy balance. Some of these CRH-expressing cell groups are located in the central nucleus of the amygdala (CeA), bed nucleus of the stria terminalis (BNST), lateral hypothalamic area, parabrachial nuclei, and dorsal motor nucleus of the vagus. Evidence from lesion studies and central injections of CRH and its antagonists suggests strongly that the central CRH system regulates not only the neuroendocrine and autonomic but also behavioral and possibly the neural recruitment responses to applied stressors.

Several studies have shown that CRH expression in the PVN is decreased by corticosteroid treatment, whereas CRH in the CeA and BNST is increased, suggesting that the corticosteroids exert opposite effects on CRH at different sites in brain. However, recent evidence suggests strongly that neurons in the PVN inhibit neuronal expression of CRH in the amygdala; that is, it is not a direct effect of glucocorticoids on extra-PVN cells that causes increased CRH expression but rather neural signals from the PVN to the amygdala that are altered by decreased or increased corticosteroids. Thus, it appears that at least some

Figure 1 The PVN is central to the stress responsive systems of brain. CRH neurons in the PVN regulate activity in the HPA axis. Neurons in the PVN also regulate autonomic nervous system activity through the innervation of the dorsal motor nucleus of the vagus (DMN-X) and the interomedial lateral cell column of the spinal cord (IML) containing sympathetic preganglionic neurons. Recent results from Palkovits et al. show that pathways from the PVN also regulate CRH expression in the central nucleus of the amygdala (CeA). Although not documented, a similar pathway may exist for CRH neurons in the bed nucleus of the stria terminalis (BNST). Solid and dashed arrows indicate stimulatory and inhibitory connections, respectively.

central CRH pathways are also affected by activity in the PVN (Figure 1). It now seems possible that signals from the PVN serve to orchestrate the activity of the rest of the central CRH system.

Characteristics of the Hypothalamic-Pituitary-Adrenal Axis

The HPA axis exhibits three prominent characteristics that interact to alter the regulation of ACTH and corticosteroid secretion: a circadian rhythm in basal activity, sensitivity to corticosteroid (F and B) feedback, and responsiveness to stressors. The response to a single stress differs considerably from responses to either homotypic or heterotypic stressors on the background of chronic stress, suggesting major regulatory changes occur in the central neural pathways that activate the HPA axis.

Circadian Rhythm of Glucocorticoid Secretion

Vertebrates exhibit peak circulating corticosteroid levels at the onset of their daily activity cycle and trough levels during the early period of inactivity. The circadian rhythm is driven by the biological clock in the suprachiasmatic nuclei in mammals and fish and in the pineal in birds. In humans and rodents, F and B levels change over a wide range between the peak and trough of the rhythm, and both peak and

trough values are regulated by negative feedback effects of F or B on hypothalamic secretion of CRH. During the trough of the rhythm in rats, it appears that there is no CRH/AVP drive from the hypothalamus because neither lesions nor passive immunization with CRH antisera changes ACTH or B secretion; by contrast, CRH(AVP) secretion is essential to drive the circadian increase in B, as shown in the same experiments. Similarly, either adrenalectomy or reduction in normal B levels by use of adrenal B synthesis inhibitors elevates ACTH at both times of day. Both ACTH and direct neural regulation appear to account for the marked circadian rhythm in the amplitude of adrenal corticosteroid production.

Corticosteroid Feedback

Feedback regulation of stress-induced ACTH secretion is markedly affected by the circadian rhythm in HPA activity. There is high feedback sensitivity at trough times and relatively low sensitivity during peak times. In rats with fixed B levels, this is independent of the corticosteroid levels at the time of stressor application, but appears to correlate with the circadian drive to the CRH neurons.

Stressors

Acute signals that alter the balance in the organism stimulate acute HPA responses. These stimuli are most often termed stressors; however, there are also HPA responses associated with stimuli to hypothalamically regulated functions, such as feeding and copulation.

Acute stressors Acute, punctate stressors such as a 30-min psychological stress in humans or a similar period of restraint in rats provoke acute HPA responses that are usually completed within 2 h (Figure 2). The intensity and duration of the acute stimulus are related directly to the magnitude of the HPA response. These acute HPA responses are also modified to an extent by glucocorticoid feedback acting in the fast and intermediate time domains on mineralocorticoid receptors (MRs) and GRs. In rats, there is a clear behavioral role of the acute rise in B acting at GR-containing cells in the amygdala to consolidate memory of aversive events.

Persistent or chronic stressors markedly alter regulation in the hypothalamic-pituitary-adrenal axis Under conditions of chronic stress, there are changes in the amplitude of circadian rhythms, with increasing intensity of stress resulting in decreases in the amplitude of the rhythm through the elevation of trough values. Moreover, the magnitude and duration of acute stress responses under conditions of chronic stress depend on familiarity with the stressor. Chronic

Figure 2 An example of typical ACTH and corticosterone (B) responses to acute restraint in naive rats not previously exposed to stressors. The duration of restraint was 30 min; thereafter rats were returned to their home cages. The ACTH response ceases at the end of restraint; because ACTH levels are high, the B response is prolonged for 30 min beyond the period of restraint.

or prior stress appears to recruit neural pathways that alter regulation of acute HPA responses.

Circadian rhythm Under resting conditions, without additional acute stress, the signs of mild chronic stress are increased trough corticosteroid levels, suggesting strongly that under chronically stressful conditions there is hypothalamic stimulation of ACTH secretion at all times of day. With increasing intensity of chronic stressors, ACTH and corticosteroid secretion is elevated above normal around the clock (Figure 3). The elevation of the trough corticosteroid values is biologically significant and has been shown to enhance glucocorticoid-dependent target responses.

Altered responses to homotypic and heterotypic stressors When acute stress is presented to chronically stressed rats, it becomes clear that marked stress-induced alterations in control of the HPA axis have occurred. In rats, it has been shown that if the acutely applied stimulus is a repetition of the chronic stimulus (homotypic stress), the duration and magnitudes of ACTH and B responses are markedly inhibited compared to the responses of the naive rat (Figure 4a; cf. Figure 2). By contrast, if the acutely applied stimulus is novel and different from the chronic stimulus (heterotypic stress), the duration and magnitudes of ACTH and B responses may be markedly facilitated compared to the responses of the naive rat (Figure 4b; cf. Figure 2). These results described for restraint as a final stimulus appear to be generalizable to other types of chronic stress followed by either homotypic stress or heterotypic stress.

Figure 3 Examples of the effects of chronic stress of differing intensity on basal cortisol concentrations in humans. These examples are collected from a number of clinical papers and show stressors ranging from aging (which some may not perceive as a stress but which bears the hallmarks of chronic stress) or brief fasting at the low end to anorexia nervosa or coronary infarction at the high end. Note that under conditions of mild stress, only the trough levels of the basal rhythm are affected; as the stimulus intensity increases, mean F levels increase until, at highest intensity, the normal circadian rhythm disappears.

Figure 4 Typical HPA responses to restraint. a, As a homotypic stressor (restraint : restraint); b, As a heterotypic stressor (cold : restraint). Clearly, homotypic HPA responses are diminished (adaptation) and heterotypic responses are exaggerated (facilitation) in chronically stressed rats compared to naïve rats exposed only to the acute stress or restraint (see Figure 2). These are representative results (relative to results in concurrently run naïve rats) from separate sets of experiments of (a) Viau and (b) Bhatnagar.

If we were dealing only with repetitions of the same stimulus, it would be appealing to suppose that the final ACTH and B responses were reduced because of the prior and repeated stress-induced increases in B and its feedback effects on brain; however, because heterotypic stimuli elicit either normal or larger than normal responses, it is clear that prior stress-induced increases in B cannot explain the effect of chronic stress on regulation of the HPA axis.

Neural pathways mediating acute hypothalamic-pituitary-adrenal responses in chronically stressed animals There must be, as well, alterations in the neural pathways that respond to homotypic and heterotypic stimuli in chronically stressed rats.

In recent years, either *in situ* hybridization or immunocytochemical techniques have been used to measure changes in immediate early gene (most usually Fos) expression with time after stressors applied

to stress-naïve rats in order to determine which neural structures are excited by specific stimuli. These studies have shown that most stimuli activate a common set of structures; among these are the nucleus of the tractus solitarius (NTS), ventrolateral medullary and pontine catecholaminergic cell groups, lateral parabrachial nuclei, raphe nuclei, locus coeruleus (LC), PVN, thalamic paraventricular nuclei (PVTh), amygdala, BNST, lateral septum, and prefrontal cortex. Recently, these techniques have been used in chronically stressed rats exposed to either a homotypic or heterotypic stressor. In both sets of experiments, the numbers of Fos immunoreactivity (Fos-ir) cells in a given structure were compared in naïve and chronically stressed rats after a final stress (foot shock : foot shock and cold : restraint). In both reports, more neurons in PVTh stained with Fos in the chronically stressed rats. In marked contrast to the increased number of Fos-staining cells in the PVTh, after homotypic stress the numbers of Fos-expressing cells in the amygdala, PVN, raphe nuclei, and LC were decreased compared to naïve rats experiencing the stressor for the first time; the reduction in Fos-ir cells in the PVN probably reflected a reduction in ACTH that generally occurs after the *n*th application of a homotypic stressor. After heterotypic stress, the opposite was observed; the numbers of Fos-positive cells in the amygdala, PVN, raphe nuclei, and LC were increased in the chronically stressed rats compared to naïve rats experiencing restraint. In this case, the increase in PVN Fos-ir cells was shown to reflect elevated ACTH responses that occurred after the heterotypic stressor.

The role of the PVTh on acute restraint-induced ACTH secretion was studied in naïve and chronically cold-stressed rats by lesions of the structure. Lesions of the PVTh augmented restraint-induced ACTH secretion in chronically stressed rats, although they had no effect on the amplitude of the ACTH response to restraint in stress-naïve rats. Thus, it appears that the PVTh normally acts to inhibit HPA activity in chronically stressed, but not naïve, rats; perhaps, therefore, the increased number of activated cells in this structure represents a memory of prior stress. Because the number of Fos-positive cells in the PVTh increases after both homo- and heterotypic stressors, it does not seem likely that this structure exhibits opposite functional effects after the two types of stressors; it is more likely that the output of the PVTh on the HPA response to acute stress in chronically stressed rats is generally inhibitory and independent of the type of acute stress.

The output of the posterior PVTh, where increased numbers of Fos-ir neurons were found after heterotypic restraint stress, is quite discrete; this portion of the nucleus innervates the basolateral nucleus of the

amygdala (BLA), basomedial nucleus of the amygdala (BMA), and CeA – also sites where decreased numbers of Fos-ir cells were found after homotypic shock stress and where increased numbers of Fos-ir cells were found after heterotypic restraint stress in cold-exposed rats. Based on Fos staining in rats after the application of homotypic and heterotypic stressors and some functional results, the diagrammatic circuit in [Figure 5](#) shows that some pathways to the activation of the HPA axis may be recruited in the chronically stressed individual.

[Figure 5](#) clearly emphasizes the major role played by the amygdala in responding to acute stress under conditions of chronic or prior stress. Only a small amount of the known anatomic connectivity is shown in the figure. For instance, both the NTS and lateral parabrachial nucleus directly innervate all the other cell groups as well as the PVTh; the LC and raphe nuclei also innervate all the other cell groups shown in the diagram; and the PVN also innervates the amygdala, LC, raphe nuclei, lateral parabrachial nucleus, and NTS. Thus, the proposed circuit is massively parallel in nature. Afferent input probably ascends primarily through parallel inputs from the NTS (and ventral medullary aminergic pathways) and the parabrachial nuclei to more anterior brain sites. It is assumed that, under conditions of both homo- and heterotypic stress, the PVTh inhibits activity in the amygdala that leads to the activation of the HPA axis as well as behavioral and autonomic activity. The raphe nuclei, through secretion of serotonin at the lateral nucleus of the amygdala, may inhibit amygdalar activity, possibly mediating HPA adaptation to homotypic stress.

Although the circuit in [Figure 5](#) is based primarily on changes in the number of Fos-positive neurons after a final application of the same or a novel stress in chronically or repeatedly stressed rats, to date there has been no attempt to identify the phenotype of the increased Fos-positive cells after the application of novel stimuli. Validation of the model shown in [Figure 5](#) will require this identification and will also require the identification of the terminal fields of the neurons whose activity is altered specifically under conditions of novel stress on a background of chronic stress.

It is clear from this discussion that chronic stress alters the central regulation of stress-induced HPA function. In addition, the altered neural emphasis also effects changes in behavioral and autonomic outputs. The altered amygdalar output that proceeds through the CeA is compatible with changes in the activity of the amygdalar CRH system, which innervates all the indicated output structures. Thus, the major central stress mediator, CRH, may be in large part responsible

Figure 5 Model of pathways that are emphasized in HPA responses of chronically stressed rats to acute homotypic or heterotypic stressors. We assume that afferent inputs excited by stress excite the brain through activating neurons in the nucleus of the tractus solitarius (NTS) and, in turn, the lateral parabrachial nucleus. Based on results of Fos immunoreactivity (Fos-ir), the number of excited neurons in the thalamic paraventricular nuclei (PVTh) is increased after both types of chronic stressors. By contrast, compared to controls, the number of Fos-ir neurons is decreased after homotypic stress and increased after heterotypic stress in amygdala (CeA, BMA, and BLA), the PVN, the locus ceruleus (LC), and the raphe nuclei. Solid and dashed arrows indicate stimulatory and inhibitory connections, respectively. Only a selected portion of the interconnectivity is shown; both NTS and the parabrachial nucleus innervate all the other structures shown and, in turn, are innervated by the other structures. Moreover, the LC and raphe nuclei innervate all other structures. Thus, this is a massively parallel system.

for the changes in HPA responsivity observed after chronic stress.

Target Sequelae of Corticosteroid Responses to Stress

Because all cell types contain GRs, corticosteroid secretion above normal levels affects function in most tissues of the body. The alterations include changes in behavior and in endocrine and immune responses as well as in intrinsic activity of individual organs. Acute HPA responses to a single application of a stressor probably have considerable utility in that the elevated corticosteroid levels ensure an adequate substrate for increased metabolic need and help to sustain blood pressure and to depress immune function. However, chronic elevations in glucocorticoid levels induced by chronic stress can be deleterious to the organism. In addition to altering the expression of many gene products in the central nervous system, the

elevation of glucocorticoid levels inhibits central catecholaminergic systems and stimulates the expression of neuropeptide Y (NPY). The diminution of enzymatic activity in catecholaminergic systems has been correlated with reduced systemic catecholaminergic function. The stimulation of NPY in the hypothalamic arcuate nucleus has been correlated with increased food intake. In addition, glucocorticoids have been shown to be required at the amygdala for the consolidation of the memory of conditioned stimuli as well as for the inhibitory action of serotonin on glutamate-induced stimulation of lateral amygdalar cell activity. Slight elevations of glucocorticoid secretion above normal inhibit activity in the thyroid, growth hormone, and gonadal axes through actions both at the central nervous system and at the pituitary and peripheral endocrine targets.

At the tissue level, glucocorticoids inhibit immune responses and protect the organism through a sequenced feedback effect from the consequences of

overactivity in this potent system. However, because the glucocorticoids also, through central nervous system effects, alter peripheral catecholaminergic activity, the effect of stress on immune system function depends markedly on when the stress, or glucocorticoid treatment, is provided in temporal relationship to the immune challenge. Thus, the literature on this subject is confusing, showing that stress, or glucocorticoids, can enhance or inhibit immune system activity. The effects of glucocorticoids on immune cells are legion. The direct effects of glucocorticoids on target tissue activity may seem somewhat simpler. By themselves, glucocorticoids are catabolic hormones; they mobilize free fatty acids and amino acids from adipocytes and muscle and cause hyperglycemia through increasing hepatic gluconeogenesis. However, glucocorticoids also enhance insulin secretion. Normally, stress decreases food intake and insulin secretion so that the catabolic effects of the glucocorticoids predominate under stressful conditions; nonetheless, the stimulation of insulin by stress-induced glucocorticoid secretion occurs. This effect is perhaps through antagonizing the hepatic effects of insulin, and it tends to remodel energy stores so that more fat and less muscle are stored under conditions of high glucocorticoid levels.

Bone loss has become a hallmark of chronic stress, depression, anorexia nervosa, or glucocorticoid treatment. Again, these effects of the glucocorticoids are dual. They act directly on bone to decrease matrix deposition and osteoblast activity and at the hypothalamic-pituitary-gonadal axis to decrease gonadal steroid production. The gonadal steroids have positive effects on bone formation, and excess glucocorticoids provide a double hit on bone by their dual actions.

In summary, the HPA axis is one arm of the central stress system defined by CRH. Chronic stressors alter the regulation of the HPA axis, possibly by increasing the emphasis on activity in CRH pathways. Although acute glucocorticoid responses to stressors can be taken as important for the maintenance of homeostasis, chronic elevations in glucocorticoid secretion appear, on the whole, to be deleterious for the organism.

Background to Hypothermia as a Stress

The Extent of the Problem of Death due to Hypothermia

Pathophysiology of Hypothermia

Glossary

<i>Cold-induced fibrillation</i>	Very rapid, irregular contractions of the muscle fibers of the heart resulting in a lack of synchronization between heart-beat and pulse, with a resultant lack of cardiac output.
<i>Cold narcosis</i>	A state of stupor, unconsciousness, or arrested activity produced by cooling.
<i>Homeotherm</i>	A warm-blooded animal such as humans that regulates its core temperature at a constant temperature (usually 37°C, or 98.6°C) irrespective of environmental temperature.
<i>Ischemia</i>	Localized deprivation of oxygen (hypoxia) and nutrients to a tissue due to interruption of blood supply.
<i>Lipid phase transition</i>	A temperature-induced change of state of the lipid component of biological membranes involving a change from a gel phase to a liquid crystal phase. These physical changes of membrane fluidity

often result in functional alterations of membrane properties.

Thermogenesis

The production of heat in the body, usually by metabolic oxidation of food substrates.

Definitions

The prefix hypo means below or under, and therm means temperature, so hypothermia literally means below normal temperature. In humans and most other mammals, normal temperature is regarded as 37°C (98.6°F), but this single value belies the fact that normal temperature in healthy individuals varies within a degree or so, depending on factors such as the site of measurement (core or exterior) and time of day (circadian rhythm). Body temperature can be measured in a variety of ways. Exterior temperatures include sublingual (under the tongue), skin, or axillary (under the armpit) measurements. Core or interior temperatures reflect the mean temperatures of the vital organs and are approximated by esophageal, rectal, tympanic membranes, and pulmonary artery measurements. In humans, normal body temperature has traditionally been set at 37°C based upon 1 million axillary measurements from 25 000 individuals carried out by the nineteenth century investigator Carl Wunderlich in 1868. Modern-day corroboration of these data has been provided by a study of 148 healthy men and women that showed a mean oral temperature of 36.8°C, with 37.7°C as the upper limit of normal.

Humans are homeothermic mammals (warm-blooded animals), which means that the core body temperature is precisely regulated and kept constant at about 37°C, irrespective of the ambient

temperature. Even though core temperature is well maintained, the temperature of the peripheral shell (skin, fat, and muscle) ranges from 31°C to 35°C, with skin temperature at 28°C to 32°C. Thermoregulation impairment, prolonged exposure to an extreme environment, or both may lead to a decrease in core temperature and the onset of a pathological state. Nevertheless, under controlled conditions in a hospital setting, hypothermia can actually be used for therapeutic advantage in a variety of medical applications since cold can also be a protective modality. Hypothermia is defined in homeotherms as the reduction of core body temperature below 35°C (95°F), and clinically has been arbitrarily graded for convenience into degrees of hypothermia, as shown in [Table 1](#).

Background to Hypothermia as a Stress

Hypothermia is a double-edged sword in that cold has been both a friend and a foe to humanity. Historically, we know that cold can be a devastating stress, as illustrated by the nineteenth century records that Napoleon watched helplessly as his army was annihilated by the bitter Russian winter. Hypothermia remains a modern-day problem, and much of what we know has been gleaned from data collected from victims of accidental hypothermia. These include victims from outdoor recreational activities in which otherwise healthy individuals succumb to injury, and even death, as a result of overexposure to the cold weather conditions, as well as victims of urban problems such as old people living in substandard accommodations without adequate heating in the winter or homeless people sleeping on the street. The latter cases introduce some complications to the interpretation of hypothermic exposure due to confounding issues such as disease, drug or alcohol abuse, or age. In sharp contrast, deep hypothermia has saved some individuals from inevitable death due to prolonged hypoxic ischemia. There are remarkable accounts of children who have been rescued and have made complete recoveries after lengthy submersion in icy water that reduced their core body temperature to below 25°C (77°F) and caused them to stop breathing for periods as long as 40 min.

Under controlled conditions, deliberate hypothermia, while still a stress, can be used as a highly effective therapeutic modality to control, or counteract, the effects of hypoxia or ischemia associated with various medical and surgical treatments. From the very earliest medical manuscripts in the third to fifth centuries BC, we know that cold was recommended as a treatment for wounds, infections, sprains, fractures, and gouty swellings and to suppress hemorrhage (uncontrolled bleeding) and head injuries. Even total body hypothermia was recommended for tetanus and convulsions. Since the 1950s, a vast literature has emerged describing the value of hypothermia in widely varying diseases, including head injury, cerebral hemorrhage, cardiac arrest, carbon monoxide poisoning, neonatal asphyxia, and eclampsia. Today, the elective use of moderate and deep hypothermia has found numerous clinical applications centered principally upon protection of the heart and brain to facilitate techniques in cardiothoracic surgery and neurosurgery. Moreover, the robust cerebroprotective effect of mild hypothermia demonstrated in animals is currently undergoing clinical trials in the management of traumatic brain injury and may in the future be applied as an adjunctive technique in other critical situations such as victims of stroke and hemorrhagic shock.

The Extent of the Problem of Death due to Hypothermia

Accidental hypothermia is regarded as an escalating problem, but accurate statistics are not readily available. This is largely due to the fact that records often do not recognize or specify hypothermia as the primary cause of morbidity or mortality in victims of accidental hypothermia. Official health statistics based on death certificates tend to underestimate the actual incidence of hypothermia. This is partly due to the use of a single-cause coding system; for example, if a death is recorded as bronchopneumonia due to hypothermia, the cause of death is recorded as pneumonia and no statistical record of hypothermia is made. The issue is further complicated by the fact that hypothermia is often not diagnosed or recognized by physicians. Nevertheless, predictions have been made that significant numbers of people die from hypothermia-related causes. For example, based upon the research of Taylor and Fox in Britain, it has been predicted that 20 000 hypothermia-related deaths occur per year, predominantly in the elderly. Similar estimates in North America predicted 25 000 hypothermia-related fatalities per year in the United States and 8 000 in Canada. There is a growing awareness of exposure hypothermia associated with

Table 1 Classification of hypothermia

<i>Classification</i>	<i>Temperature range (°C)</i>	<i>Temperature range (°F)</i>
Mild	32–35	90–95
Moderate	27–32	81–90
Deep or profound	10–27	50–81
Ultraprofound	<10	<50

recreation, cold water immersion, and to some extent socioeconomic problems among people with predisposing factors such as drugs, alcohol intoxication, and age. However, attention also needs to be given to secondary hypothermia, such as that induced during shock resulting from trauma.

Pathophysiology of Hypothermia

Systemic Effects of Hypothermia

Surviving hypothermic exposure in humans is generally associated with core temperatures above 25°C (77°F); however, surviving deeper exposure is possible if appropriate treatment is employed. Physiological responses to cooling and warming depend on how heat exchange is mediated and whether the patient is conscious or anesthetized. Heat exchange may be either by surface phenomena (conduction, convection, and radiation) or in the clinical setting by core perfusion techniques. The pathophysiology and treatment of accidental hypothermia victims are complex issues often compounded by the nonhomogeneity of the patient population. For example, a drowning person may become seriously cooled in a matter of minutes, while elderly people living in substandard accommodations may undergo an insidious cooling process that develops over several weeks. Under these circumstances it has proved difficult to compare different methods of treatments. However, in the comparatively controlled environment of the hospital operating room, the physiological responses to hypothermia are well characterized and documented.

Effect of hypothermia on thermoregulation Hypothermia triggers an ordered progression of autonomic thermoregulatory responses. Initially, cutaneous vasoconstriction is initiated in the arteriovenous shunts of the extremities, mediated by noradrenergic sympathetic nerves. With moderate cooling, this reflex vasoconstriction of the skin is assisted by direct constrictor action of cold on the arterioles. Aided by reflex noradrenergic drive to the heart, the vasoconstriction can result in large increases in arterial pressure. So, the body tightly controls its core temperature, using its peripheral shell as a thermal buffer with the environment. As heat is lost from the periphery, the temperature gradient from the core to the periphery increases, and heat flows out of the core tissues into the peripheral shell. Eventually vasoconstriction can no longer compensate for the continuing heat loss of the periphery by sacrificing peripheral temperature, and shivering is necessary to maintain core temperature. With progressive cold exposure, reflex increases in muscle tone and shivering are

brought about by somatic motor nerves, and this can increase heat production by as much as fivefold for many hours at a time. Interestingly, newborn infants do not shiver, but utilize a nonshivering thermogenesis that relies upon metabolic heat production from the oxidation of brown fat. In general, when hypothermia reaches moderate degrees (<33°C), shivering gradually decreases and is followed by stiffness of muscles and joints.

Effect of hypothermia on the heart and brain Hypothermia has significant effects on nearly every organ system, but disturbances of cerebral and cardiac function as the temperature of the brain and heart fall below 35°C (95°F) are of most concern. One of the earliest signs of hypothermia is a change in personality. The individual may become uncooperative and show signs of listlessness, incoordination, and confusion, often with subsequent amnesia for events at the time of low body temperature. Loss of consciousness is highly variable and may occur at any point within the range 26–33°C. After an initial rise in cardiac output associated with shivering, cardiac function declines with slowed heart rate due principally to the direct effects of cold on the cardiac muscle. At temperatures between 17 and 26°C (63 and 79°F), the cardiac output is not sufficient to supply even the reduced oxygen requirements of the cold tissues. At 25°C (77°F), cardiac function is reduced to about 30% of normothermic levels. The most important and life-threatening complication of hypothermia is the associated cardiac irritability. Progressive cooling eventually causes cardiac arrhythmias, with atrial fibrillation occurring earlier (~30°C [~86°F]) than ventricular fibrillation (threshold at 28°C [82°F]). However, the latter is highly variable and is influenced by several factors, including acid–base balance. Rapid cooling of large, aged, or diseased hearts can predispose to early fibrillation, while small, immature hearts may not fibrillate at all during cooling but pass directly from bradycardia (slow heart rate) to diastolic arrest. Ventricular fibrillation may occur in the temperature range 20–27°C (68–81°F) and is the most dangerous and feared aspect of hypothermia, since death invariably ensues unless rewarming and defibrillation procedures are initiated.

The brain is a highly metabolic tissue requiring a constant supply of oxygen and, like the heart, is exquisitely sensitive to hypoxia and ischemic insult. Metabolism is markedly suppressed by a fall in temperature, and in general metabolic rate is decreased by 5–7% per degree Celsius. Oxygen consumption is a reasonable measure of metabolic activity, since for practical purposes, tissue and cellular stores of oxygen do not exist, and cells rely upon the circulation to

deliver oxygen in quantities determined by the rate of O₂ consumption. Cerebral blood flow (CBF) and cerebral metabolic rate of oxygen consumption also decrease by about 50% for every 10-degree drop in temperature. This correlates with declining electrical activity (EEG) as the brain cools with electrocerebral silence (no measurable electrical activity) at ~20°C. This profound effect of hypothermia on diminished oxygen demand is actually one of the most important protective aspects of clinical hypothermia. However, despite the unequivocal fact that hypothermia protects the brain from the effects of hypoxia, prolonged survival in hypothermia almost totally depends on having sufficient cardiovascular function for adequate perfusion of important organ systems for supply of substrates in addition to oxygen. Hypothermia also causes a shift of the oxygen-hemoglobin dissociation curve to the left, thus reducing tissue oxygen availability. This may contribute to the uncompensated metabolic acidosis that is commonly observed with hypothermia due to reduced tissue perfusion with accumulation of lactate and other acid metabolites.

Effect of hypothermia on respiration The rate of respiration decreases progressively during cooling to 30°C, but the partial pressure of oxygen remains essentially normal. CO₂ production is significantly elevated initially due to intense shivering, but as the core temperature falls, CO₂ production is diminished. Coupled with increased solubility of CO₂ in plasma at lower temperatures, this tends to decrease the partial pressure of CO₂ despite diminished respiratory rate. The net effect of these changes is a mild respiratory alkalosis in the early phase of acute hypothermia. This alkalosis is, however, gradually replaced by metabolic acidosis as cooling progresses, due to poor tissue perfusion and oxygenation, as discussed earlier. So, in general, respiration is depressed during hypothermia, but the rate is almost in proportion to metabolic needs until respiration becomes shallow and erratic and eventually stops in the region of 25–30°C.

Effect of hypothermia on the blood Hypothermia also results in marked hematological perturbations such as increased viscosity, leukopenia (abnormally low number of circulating leukocytes), and thrombocytopenia (reduced numbers of platelets leading to bleeding tendencies). Increasing blood viscosity, which changes by as much as 5% per degree Celsius, also contributes to an apparent rise in vascular resistance (decreased efficiency of vascular perfusion). Deep hypothermia also hinders clotting by slowing the enzyme-mediated coagulation cascade and by promoting fibrinolysis. Abnormalities in clotting

mechanisms occur in 68–100% of patients subjected to clinical hypothermia, making bleeding tendencies a major concern in people subjected to prolonged hypothermia.

Physiological signs and symptoms of cold exposure Hypothermia is now recognized as the number one killer of outdoor recreationalists, and along with this has come the need for increasing awareness of the problem. As a consequence, many outdoor organizations are taking active measures to educate their members about hypothermia as an environmental hazard and are teaching emergency care for hypothermia. A critical part of this process is the ability to recognize the signs and symptoms of hypothermic exposure. [Table 2](#) illustrates some of the characteristic signs and symptoms at various stages of hypothermia.

Because survival after cold exposure is critically dependent on early intervention to reverse the effects of hypothermia, emergency personnel have become increasingly skilled over the past several years at managing and treating victims of hypothermia. It is beyond the scope of this article to describe the recommended treatments for victims of accidental hypothermia, but [Figure 1](#) illustrates an algorithm of recommended actions. It is noteworthy that some early interventions can be initiated in the field, while more aggressive treatments can not be considered until the patient is transferred to an adequately equipped emergency vehicle or hospital.

Enhancing tolerance to cold exposure The risk of accidental hypothermia is ever present for people who live at high altitudes, and efforts to protect against cold exposure have focused on methods of decreasing heat loss by improving insulation. Nevertheless, some research has been devoted to finding ways of improving cold tolerance by modifying the thermoregulatory response to cold. The principal strategies employed have been thermal acclimation, physical exercise, dietary enhancement of thermogenesis, pharmacological enhancement of thermogenesis, and manipulation of the thermoregulatory set point. While none of these approaches have been accepted routinely to improve cold tolerance, it can be concluded from some studies that the pharmacological enhancement of cold thermogenesis using ephedrine in combination with methylxanthine represents the most promising method for delaying the onset of hypothermia in humans.

Contrasting outcome between victims of accidental hypothermia and patients experiencing clinical hypothermia In considering the chances of survival after the stress of hypothermia, an important

Table 2 Characteristics of hypothermic stress at different stages of cooling

Stage	Core temperature	Signs and symptoms
Mild hypothermia	37–35°C (98–95°F)	Normal, shivering can begin, cold sensation, goose bumps, unable to perform complex tasks with hands, shiver can be mild to severe, hands numb
Mild–moderate hypothermia	35–33°C (95–93°F)	Shivering/intense, muscle incoordination becomes apparent, movements slow and labored, stumbling pace, mild confusion, may appear alert. Use sobriety test; if unable to walk a 30-foot straight line, the person is hypothermic
	33–32°C (93–90°F)	Violent shivering persists, difficulty speaking, sluggish thinking, amnesia starts to appear, gross muscle movements sluggish, unable to use hands, stumbles frequently, difficulty speaking, signs of depression, withdrawn
Moderate hypothermia	32–30°C (90–86°F)	Shivering stops, exposed skin blue or puffy, muscle coordination very poor, inability to walk, confusion, incoherent/irrational behavior, but may be able to maintain posture and appearance of awareness
	30–27°C (86–82°F)	Muscle rigidity, semiconscious, stupor, loss of awareness of others, pulse and respiration rate decrease, possible heart fibrillation
Deep hypothermia	27–25°C (82–78°F)	Unconscious, heart beat and respiration erratic, pulse may not be palpable
	<25°C (<77°F)	Pulmonary edema, cardiac and respiratory failure, death (death may occur before this temperature is reached)

Adapted from the Princeton University Outdoor Action Guide, with permission.

distinction has to be made between accidental hypothermia and clinical hypothermia. Even though the final core temperature of the individual may drop to the same level, the survival rate from clinically induced hypothermia is much higher than that of accidental hypothermia. In the latter case, homeotherms respond to hypothermic stress with immediate activation of heat production as well as inhibition of heat loss. The timing and intensity of the thermogenic response, as well as the duration over which the process can be maintained, depend on factors such as sex, age, and health of the individual. Hypothermia ensues when maximum thermogenesis fails to balance minimum heat loss and heat deficit results. As hypothermia progresses, cold narcosis of the central nervous system supervenes and respiratory support declines. Heart rate also slows with decreasing temperature, but the heart may continue to beat for some time depending upon the cooling rate. Eventually, when the core temperature drops to a specific level (in the range 15–25°C [60–77°F]), the heart either goes into ventricular fibrillation or arrests. In the battle to maintain core temperature, the subject has exhausted itself.

In contrast to the preceding scenario, clinically induced hypothermia is a sedate, relatively nonstressful, and intensively monitored condition. The patient is initially anesthetized and rapidly cooled, often with the aid of cardiopulmonary bypass support, with little or no metabolic resistance. Moreover, the patient is monitored continuously throughout so that presenting complications can be corrected expeditiously or rewarming employed before they become lethal. It is important to explain why hypothermia is sometimes induced electively in patients for clinical

benefit. As described in the next section, it has long been known that hypothermia is a highly effective modality for protecting cells against the deleterious effects of hypoxia and ischemia. In general, the extent of protection is directly related to the degree of hypothermia, with colder temperatures offering greater protection. This is based on the fundamental effect of cooling on biophysical and biochemical processes as molecular activity and mobility is slowed. In the fields of cardiovascular surgery, neurosurgery, and more recently in trauma medicine, there is often a need in complicated cases for the surgeon to implement a temporary cessation of blood flow to the heart or the brain. Adjunctive hypothermia is often used to protect the organs against hypoxia and ischemia. In recent years, there has been a renewed interest in the application of mild to moderate hypothermia as a potent neuroprotective modality, and consideration is being given to a potential therapeutic benefit of hypothermia to avert the complications of traumatic brain injury and stroke.

Cellular Responses to Hypothermic Stress

A complete understanding of the effects of hypothermia on the body calls for examination of the events at the cellular level, since this is where the pathophysiology of hypothermic stress is ultimately mediated. A great deal is known about the effects of cold on cells, since cooling has proved to be the foundation of nearly all effective methods of protecting and preserving cells and tissues for applications such as transplantation. Transplantation science calls for effective methods of preservation since donor cells, tissues, and organs are required to withstand a period of ischemia and hypoxia as part of any transplantation

Figure 1 Algorithm for treatment of hypothermia. Notes: (1) This may require needle electrodes through the skin. (2) Many experts think that these interventions should be done only in hospital, though practices vary. (3) Methods include electric or charcoal warming devices, hot water bottles, heating pads, radiant heat sources, and warming beds. (4) Esophageal rewarming tubes are widely used internationally and should become available in the United States. Abbreviations: VF, ventricular fibrillation; VT, ventricular tachycardia; CPR, cardiopulmonary resuscitation; IV, intravenous. This algorithm is based on the Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiac Care published by the American Medical Association (*JAMA*, **268**, 2171, Copyright 1992, American Medical Association, all rights reserved) and is adapted from the article 'JAMA protocol for hypothermia' at <http://hypothermia.org/jama.htm>

procedure when the blood supply is temporarily interrupted. The basis of this hypothermic protection is that cooling can help to combat the deleterious effects of ischemia, but the consequences of cooling are not exclusively beneficial, such that hypothermic storage is a compromise between the benefits and detriments of

cooling. In the following, the detrimental effects only of hypothermic stress on cells is outlined.

General suppression of reaction rates The fundamental basis of all biological and chemical processes is molecular activity and mobility, which are

governed by thermal energy such that as temperature is lowered, molecular motion is slowed. The removal of heat from a system slows down both physical and chemical processes in proportion to the loss of heat and therefore to the fall in temperature. Since the processes of deterioration associated with ischemia and anoxia are mediated by chemical reactions, it has proved well founded to attempt to prevent or attenuate these changes by cooling. Biochemical processes involve molecular interactions that are invariably catalyzed by enzymes in reactions that require energy input from cellular stores such as ATP or creatine phosphate. Cooling can affect all components of these reactions, including the energy status of the substrate molecules, the stability of the enzyme protein, and the capacity of the cell to supply biological energy. The rate of biophysical processes such as diffusion of ions and osmosis declines linearly with temperature by approximately 3% per 10°C. It is apparent, therefore, that biophysical events are relatively little affected by the comparatively modest temperature changes imposed during hypothermic storage of tissues for transplantation. It is only at much lower temperatures that the rates of biophysical processes become significantly important, especially at sub-zero temperatures, when phase changes lead to both ice formation and solute concentration changes.

By comparison, the rate of chemical reactions, including the biochemical processes that constitute metabolic activity, is slowed significantly more by a given degree of hypothermic exposure. It is well established that within the temperature range 0–42°C, oxygen consumption in tissues decreases by at least 50% for each 10°C fall in temperature. The quantitative relationship between energy requirements for biochemical processes and temperature changes has been expressed mathematically in different ways:

1. The Arrhenius relationship: Biochemical processes, in common with all chemical reactions, occur only between activated molecules, the proportion of which in a given system is given by the Boltzmann expression, $\exp(-E/RT)$, where E is the activation energy, R is the gas constant, and T is the absolute temperature. According to the Arrhenius relationship, the logarithm of the reaction rate, k , is inversely proportional to the reciprocal of the absolute temperature:

$$-\log k = A(-E/2.3RT).$$

A graphical plot of $\log k$ against $1/T$ will yield a straight line with a slope of $E/2.3R$ if the relationship represents a single rate-limiting step.

2. The Van't Hoff rule relates the logarithm of a chemical reaction rate directly to temperature and is commonly expressed in the form of the respiratory quotient or temperature coefficient, Q_{10} , where Q_{10} is the ratio of reaction rates at two temperatures separated by 10°C. Accordingly,

$$Q_{10} = (K_2/K_1)10^{(T_2-T_1)}$$

For most reactions of biological interest, Q_{10} has a value between 2 and 3, but some complex, energy-dependent reactions have a Q_{10} between 4 and 6 and are more likely to stop completely at low temperatures. Both Q_{10} and Arrhenius plots have been used to quantitate changes in metabolic processes occurring in biological systems, whether they are enzyme reactions in single cells or the oxygen consumption of the entire human body. The Q_{10} for whole-body oxygen consumption is approximately 2, indicating that, in general, metabolic rate is halved for each 10°C drop in temperature.

Metabolic uncoupling While it is clear that cooling has a profound effect on biochemical reaction rates and that this in turn can slow degradative processes and reduce the rate of substrate and energy depletion, it is important to realize that not all reaction rates are affected to the same degree, or even in the same manner, by cooling. One hypothesis of chilling injury states that at a certain critical temperature within the chilling injury range, the membrane lipids undergo a transition from a liquid-crystalline to a solid gel state. The two main consequences of the transition thought to eventually result in cell injury are an increase in membrane permeability and an increase in the activation energy of membrane-bound enzymes such as those controlling respiration in mitochondria. Thus, the result would be the accumulation or depletion of metabolites at the point of entry into mitochondria. Hence, the membrane phase transitions in subcellular membranes could cause metabolic imbalance and provide one component of injury sustained by homeothermic cells during cold exposure.

Figure 2 shows schematically the large number of different, integrated chemical reactions that constitute common metabolic pathways within a cell. Each of these reactions will be affected by cooling in a different manner and to a different degree such that the possibility exists for uncoupling reaction pathways and producing harmful consequences. In preservation, cooling prolongs *in vitro* survival because it slows metabolism, reduces the demand for oxygen and other metabolites, and conserves chemical

Figure 2 Schematic diagram illustrating the complexity of integrated biochemical pathways responsible for the structural and functional integrity of a typical cell. A healthy cell depends upon the synthesis and degradation of a wide variety of molecules. These processes are controlled by a complex series of biochemical reactions that produce and consume energy in a highly regulated manner. The diagram portrays schematically the complex integrated pathways that constitute the biochemical machinery of a typical cell. About 500 common metabolic reactions are shown by the connecting lines, with each metabolite represented as a filled circle. The centrally placed reactions of the main energy-producing pathways (glycolysis and tricarboxylic acid cycle) are shown as bold. A typical mammalian cell synthesizes more than 10 000 different proteins, a major proportion of which is enzymes. Each of these pathways can be affected differently by reduced temperatures such that the possibility exists for disruption of the normal metabolic processes, with harmful consequences as described in the text. energy. However, it does not affect all reactions to the same extent, and the net result of cooling on an integrated, metabolizing system is complex, not entirely predictable, and not completely understood.

Studies of the effects of pure hypothermia on cell viability in the absence of any prior hypoxia have shown that the inactivation (killing) rates of cells exposed to reduced temperatures change slope at approximately 7–8°C, implying that there are distinct

mechanisms of hypothermic inactivation above and below this transition temperature. These values have been interpreted as suggesting that unbalanced metabolism is probably the rate-limiting step for hypothermic inactivation in the higher temperature range (8–25°C), and membrane lipid phase transition or cold denaturation of a critical protein is likely to be responsible for the strong temperature dependence in the lower range (<8°C).

Effect upon energy metabolism Under normal circumstances the supply of energy-rich compounds to fuel a cell's requirement for homeostatic control is continuously replenished by oxidative phosphorylation in the mitochondria. During cooling, however, there is a progressive exhaustion of chemical energy reserves in a cell despite the general suppressive effect of cooling on metabolism. The effect of cooling on metabolism is complex and should not be regarded as causing a simple uniform retardation of all biochemical reactions. For example, the complexity of low temperature effects on mitochondrial respiration is not limited to the impairment of translocase enzymes. It has been shown that other enzymes that control reactions of the tricarboxylic acid (TCA) cycle and the electron transport chain are affected differently by cold storage.

Effect upon ion transport and cell swelling Intracellular ionic composition and volume regulation of a cell are maintained by a pump-leak mechanism in which membrane-bound enzymes transport various ions and solutes to counter the passive diffusion driven by chemical potential gradients. These active pumps are inhibited by hypothermia both by its direct effect on enzyme activity and by the depletion of high-energy reserves as mitochondrial energy transduction fails. Nevertheless, the resultant passive redistribution of ions and water across the cell membrane and the concomitant change in the membrane potential have been demonstrated to be rapidly and fully reversible in the short term and may not be a source of permanent injury. Cells are known to have interrelated cation transport systems depending on energy supply and are thereby affected by reduced temperatures. Moreover, it is recognized that changes in the distribution of divalent cations (Ca^{2+} , Mg^{2+}) as a consequence of ischemia, hypoxia, and even cooling are especially important in cellular injury. The belief that calcium, in particular, is a mediator of cell death is based upon evidence accumulated over several decades from observations in a wide variety of tissues and pertains to cell death from a variety of causes. Cytosolic calcium concentration is 10 000-fold lower than extracellular concentrations, and it is now postulated that enhanced or unbalanced calcium influx across the plasma membrane represents a final common pathway in cell death mediated by various conditions that share the tendency to induce an abnormal membrane permeability for calcium. In recent years, the recognition of the central role of calcium-mediated effects in the death of cells of ischemically sensitive tissues such as heart and brain has led to intense scrutiny of the effects of perturbations in divalent cation homeostasis. Calcium functions as a

second messenger in the regulation of numerous biochemical and physiological processes, often by activating regulatory proteins, which, in turn, can activate many intracellular enzymes, including protein kinases. It has recently been proposed that the significant protective effect of mild hypothermia against ischemic brain injury might be mediated in part by inhibition of calcium-induced effects and the prevention of inactivation of important Ca-dependent enzyme systems such as the kinases. However, it is generally recognized that cooling has no beneficial effect in preventing, and may even accentuate, inhibition of the (Ca^{2+} , Mg^{2+})-ATPase pump mechanism, which in general is the most important factor in controlling intracellular Ca^{2+} concentrations. The effects of cooling on calcium homeostasis result not only from the inhibition of transmembrane pumping, but also from the inhibition of calcium sequestration by intracellular organelles, particularly the endoplasmic reticulum and mitochondria.

Proton activity changes The principal events of the ischemic cascade show that elevation of the concentration of protons, i.e., increasing acidity, is regarded as a contributory central event in the process of cellular injury ensuing from O_2 deprivation and energy depletion. Moreover, reduced temperatures are also known to influence pH regulation, which is another important homeostatic mechanism for cell survival. It has frequently been reported that hydrogen ion concentration increases in a variety of mammalian cells during hypothermic storage such that tissue pH has been recorded to fall to 6.5–6.8 within a few hours of cold. Acidity is widely recognized as a hazard for cells, with the accumulation of protons contributing to a variety of deleterious processes, including metabolic block of glycolysis and structural damage. Destabilization of lysosomes releasing harmful proteases and catalysis of oxidative stress by mobilization of free heavy metals have been implicated as mechanisms of cellular tissue injury during acidosis.

Effect of hypothermia on the generation of oxygen free radicals The emerging role of oxygen-derived free radicals (ODFRs) in tissue injury and their participation in reperfusion injury is well established. In essence, it is recognized that cooling increases the susceptibility of cells to produce free radicals and attenuates the natural defense mechanisms by which cells normally deal with the low-level free radical production in metabolism. Due to a lower activation energy, free radical reactions are depressed less by temperature reduction than the enzymatic processes used to scavenge them. It is the balance between production and removal of free radicals that is crucial

to the cell such that a combination of excessive radical generation and hindrance of normal defense mechanisms can redirect the processes in favor of injury. There is evidence that some of the natural defense mechanisms against free radicals become depleted during cold storage and that the addition of natural pharmacological scavengers including superoxide dismutase (SOD), catalase, or mannitol to cold storage media may improve the viability of hypothermically stored organs. It is clear, therefore, that in tissues exposed to cold there is potential for unbalanced free radical reactivity and elevated intracellular free calcium levels, and subsequent warming and reperfusion is likely to greatly potentiate these adverse events.

Structural changes The interrelationship between structure and function is fundamentally important for cellular homeostasis, which is governed by an intricate array of biochemical, physiological, and biophysical processes. Moreover, these processes are compartmentalized within the cell such that the structure of biological membranes and the cytoskeleton are integral components of cell viability and vitality.

The sensitivity of biological structures to temperature change is well known, and the thermal denaturation of proteins in particular is well documented. Thus, most proteins, as well as nucleic acids and many polysaccharides, are able to exist in their biologically active states only within a limited temperature range that is characteristic of the macromolecule and its environmental conditions such as ionic strength and pH. While a great deal more is known about heat denaturation of proteins at elevated temperatures, there are well-described examples of cold denaturation involving spontaneously unfolding of proteins or dissociation of the multisubunit structure into biologically inactive species that may or may not reassemble on rewarming to normal temperatures.

It has been postulated on the basis of measurements in both model systems and intact cells that a phase separation occurs within the plane of the membrane as cooling proceeds. Such cold-induced changes in the degree of membrane fluidity render it thermodynamically unfavorable for membrane proteins to remain in the gel phase such that they may be redistributed laterally into regions of low melting point lipids that remain in the liquid crystalline phase. This process is thought to result in packing faults due to the development of lipid-rich and protein-rich microdomains in a membrane undergoing phase transitions. One consequence of this could be a change in membrane permeability and alteration in the solute barrier function of the membrane. Phase separation of mammalian membranes has been demonstrated at temperatures

in the region of 10°C and below, and this correlates with the trend toward increased permeabilities to both ions and even large molecules such as proteins during cooling. In addition to phase separations, other forms of cold-induced membrane damage include the actual loss of membrane phospholipids, which is intuitively more deleterious than phase changes, which may in large part be reversible.

Cold-induced changes of cellular structural proteins that constitute cytoskeletal components such as microtubules have been known since the mid 1970s. This cold sensitivity appears to be mediated by depolymerization of component polypeptide units and in general is readily reversible upon rewarming. Nevertheless, the possibility exists for reassembly of the microtubules in a way that results in cellular abnormalities.

Thermal shock It has been discovered in some cells that the rate of cooling is also a determinant of injury; the phenomenon, which is not well understood, is referred to as thermal shock (cold shock) or chilling injury. The effects are thought to be related to the thermotropic properties of cell membranes involving phase transitions, as discussed briefly earlier. It has been proposed that rapid cooling in the absence of freezing can cause mechanical stresses on membranes induced by differential thermal contraction.

Cold shock proteins Changes in the structure of proteins are a common response to stress such that cells accumulate incorrectly folded proteins as a consequence of stresses such as hypoxia or temperature change. Proteins that experience unfolding or conformational changes do not remain soluble and are transformed into denatured proteins. It is now well established that one of the defense mechanisms adopted by cells to counteract such effects of stress is to synthesize new proteins commonly referred to as stress proteins or heat shock proteins (HSPs) because of their increased synthesis by many cell types after exposure to elevated temperatures. The general role of this group of highly conserved stress proteins is believed to be homeostatic in that they protect the cell against the harmful consequences of traumas and help promote a quick return to normal cellular activities once the shock has terminated.

The induction of stress proteins in response to cold (cold shock proteins) has been identified in invertebrate species such as bacteria and yeast, but it was not known until recently that similar families of cold shock proteins are also induced in mammalian cells.

Apoptosis vs. necrosis in cold-induced cell death It is now known that there are two distinct ways in

which cells may die. Necrosis is caused by a general failure of cellular homeostatic regulation following injury induced by a variety of deleterious stimuli, including hypoxia, toxins, radiation, and temperature changes. Apoptosis (programmed cell death) by contrast, is a regulated process that has been distinguished from necrosis by numerous morphological, biochemical and physiological differences. While many of the diverse stresses known to cause necrotic cell death have also been reported to induce apoptosis in a variety of cells, the role of low temperatures as a possible stimulus of programmed cell death has yet to be investigated in depth. Nevertheless, it has been shown that cultured mammalian fibroblast cells at the transition from logarithmic to stationary growth were killed by brief exposures to 0°C and rewarming at 37°C. Moreover, the kinetics of cell death served to distinguish cold-induced apoptosis from the lethal effects of longer-term cold storage (hours or days), and also showed characteristics inconsistent with direct chilling injury (cold shock). It is possible, therefore, that apoptosis may represent another manifestation of cold injury. Susceptibility to cold-induced apoptosis seems to depend critically upon cell growth cycle and the temperature of exposure. Recent studies in cultured hepatocytes and liver endothelial cells have indicated that reactive oxygen species (free radicals) might play a key role in mediating cold-induced apoptosis.

Finally, it is important to emphasize that both the severity and the reversibility of the catalog of effects outlined here are highly dependent upon both the duration and the extent of hypothermic exposure. Many of the consequences of hypothermic stress manifest in cells subjected to prolonged exposure during cold storage do not develop during brief exposure to mild or moderate hypothermia.

Introduction

Thyroid and Psychiatric Symptoms

Types of Hypothyroidism

Clinical Hypothyroidism

Subclinical Hypothyroidism

Thyroid in Psychiatric Illness

Glossary

Clinical hypothyroidism A disorder characterized by decreased production of thyroxine and triiodothyronine by the thyroid gland. It leads to a well-recognized clinical syndrome, of which psychiatric symptomatology is a prominent component.

Depressive symptoms A group of mood, cognitive, and physical symptoms that commonly occur, but the number of symptoms are insufficient to qualify for the diagnosis of major depression.

Major depression A characteristic syndrome that consists of mood, physical, and cognitive symptoms. This is one of the commonest psychiatric illnesses and is amenable to treatment with antidepressants and specific psychotherapies.

Subclinical hypothyroidism A condition characterized by normal levels of circulating thyroxine and triiodothyronine but elevated levels of thyrotropin (TSH). There is also an enhanced TSH response to thyrotropin-releasing hormone (TRH). A well-described clinical syndrome is usually not evident.

Thyrotropin (TSH) A hormone secreted by the pituitary that acts on thyroid cells to stimulate the production of thyroxine and triiodothyronine; also called thyroid-stimulating hormone.

Thyrotropin-releasing hormone (TRH) A tripeptide hormone released by the hypothalamus that stimulates the release of TSH from the pituitary. TRH and TSH play an important role in the regulation of thyroid hormone secretion, both through a stimulatory effect on the thyroid and by negative feedback regulation of circulating thyroid hormone

levels on the hypothalamus and pituitary. In this manner, appropriate thyroid hormone levels are maintained in the circulation.

Thyroxine (T_4)

One of two main circulating thyroid hormones produced by the thyroid gland. Although it is the major secretory product of the thyroid gland, this hormone is thought to exert its physiological action by conversion to triiodothyronine.

TRH test

A diagnostic test that involves the intravenous administration of TRH and the measurement of TSH at 15-min intervals for 90 min. In hypothyroidism, the TSH response to TRH is exaggerated, consistent with the high output of both TRH by the hypothalamus and TSH by the pituitary in response to a failing thyroid and decreased circulating T_4 and triiodothyronine levels. With the advent of new highly sensitive tests for the measurement of TSH, the TRH test is becoming obsolete.

Triiodothyronine (T_3)

One of two main circulating thyroid hormones produced by the thyroid gland. Only approximately 15–20% of circulating T_3 is secreted directly by the thyroid; the remainder comes from conversion from T_4 . T_3 is approximately four times more metabolically active than T_4 .

Introduction

Thyroid diseases, both hyperthyroidism and hypothyroidism, are among the commonest endocrine disorders seen in clinical practice. Excess or diminished production of thyroid hormone leads to the clinical syndromes of hyperthyroidism and hypothyroidism, respectively. A systematic evaluation of thyroid function tests helps verify the role of thyroid disease in the production of this symptomatology. This article reviews the clinical and biochemical features of hypothyroidism and, in particular, its relationship to psychiatric symptomatology.

Thyroid and Psychiatric Symptoms

It has long been known that there is an association between alterations of thyroid function and psychiatric symptomatology. Clinical thyroid diseases are commonly associated with psychiatric symptomatology, particularly alterations of mood and

cognition. In particular, the association between hypothyroidism and depression has been documented consistently in the medical literature for more than 100 years.

Both hyperthyroidism and hypothyroidism may present with psychiatric symptomatology. In hyperthyroidism, a broad range of psychiatric symptomatology may present, but in hypothyroidism, depression and alterations of cognition are observed most commonly. Symptoms of anxiety and even psychosis are much less frequent. The observation of this very strong relationship between thyroid dysfunction and psychiatric symptomatology has led to the conclusion that thyroid hormones or the thyroid axis may be important in the pathophysiology of primary psychiatric disorders, especially major depression and the dementia disorders. As a result, it is common clinical practice to do a routine thyroid screening in patients who present with psychiatric symptoms, particularly disorders of mood or cognition. The best evidence is that most patients with depressive or dementia illnesses are euthyroid, and it has even been questioned whether routine thyroid screening of psychiatric patients is cost effective. However, this practice prevails because it does present an important opportunity, however uncommon, to identify an easily reversible major psychiatric disorder associated with hyper- or hypothyroidism.

Types of Hypothyroidism

Hypothyroidism is categorized according to the degree of thyroid failure. Since the mid-1970s, the definition of various degrees of hypothyroidism has become standardized. Grade I, or clinical, hypothyroidism is characterized by clinical symptoms of thyroid underactivity and is associated with abnormally decreased levels of thyroxine (T_4) and triiodothyronine (T_3), elevated basal thyrotropin (TSH) levels, and an enhanced TSH response to thyrotropin-releasing hormone (TRH). In grade I hypothyroidism, clinical symptoms of thyroid hormone deficiency are clearly evident. In grade II hypothyroidism, peripheral T_4 and T_3 levels are within normal limits, but both basal and TRH-stimulated TSH levels, using the TRH test, are elevated abnormally. Patients with this type of hypothyroidism do not have the classic symptoms of clinical hypothyroidism. Grade III hypothyroidism is characterized by no clinical features of hypothyroidism, normal circulating levels of T_4 , T_3 , and basal TSH, but an abnormally elevated TSH response to TRH. Each of these subtypes of hypothyroidism is considered separately here.

Clinical Hypothyroidism

Clinical hypothyroidism is a relatively uncommon disorder affecting approximately 1% of the population. However, its prevalence is influenced strongly by both gender and age; it is substantially more common in women and also increases in prevalence with advancing age. Therefore, the prevalence of clinical hypothyroidism in women over the age of 60 is approximately 4%. The features of clinical hypothyroidism are often vague and nonspecific. They include symptoms such as facial puffiness, dry skin, hair loss, myalgia, paresthesias, reduced tendon reflexes, cold intolerance, constipation, and fatigue. However, psychiatric symptoms occur in the majority of patients and are reasonably consistent for diagnosis. They include depressive symptoms or even a major depressive syndrome and, less commonly, evidence of cognitive deterioration. Anxiety and psychotic symptoms are much less common. The consistency of the psychiatric presentation in clinical hyperthyroidism is remarkable and highlights a need to exclude clinical hypothyroidism as a primary diagnosis in all patients presenting with depression or dementia, particularly in the elderly. These psychiatric syndromes associated with clinical hypothyroidism are generally not amenable to treatment with psychotropic drugs such as antidepressants and require correction of the underlying thyroid disease. However, in a minority of patients, psychiatric symptoms may persist even with correction of the underlying endocrine disorder, and further intervention with psychotropics may be necessary.

The diagnosis of clinical hypothyroidism is established on the basis of the clinical history as well as the measurement of T_4 , T_3 , and TSH. The specific treatment is dependent on the underlying pathology. However, thyroid replacement therapy is necessary to restore normal thyroid function.

Subclinical Hypothyroidism

This refers to both grade II and grade III hypothyroidism, as defined earlier. These abnormalities of thyroid function are usually detected on routine thyroid screening and are not associated with any particular clinical syndrome. Approximately 5–15% of depressed patients have evidence of subclinical hypothyroidism. These cases of subclinical hypothyroidism may be associated with a variety of causes, particularly iodine deficiency, autoimmune thyroid disease, and, less commonly, ablation treatment of clinical hyperthyroidism. The medical consequences of subclinical hypothyroidism are uncertain. Most studies have focused on grade II hypothyroidism, and these

suggest that patients may have alterations in some physiological parameters such as myocardial contractility that may be reversed by thyroid hormone replacement therapy. Other studies have suggested that grade II hypothyroidism may be a risk factor for coronary artery disease due to alterations in serum lipoproteins. Although the clinical implications of grade II hypothyroidism require further clarification, it is known that between 5 and 10% per year of patients with subclinical hypothyroidism progress to clinical hypothyroidism.

The psychiatric consequences of subclinical hypothyroidism also remain to be clarified. As noted previously, approximately 5–15% of depressed patients have grade II or III subclinical hypothyroidism, although it is unclear whether this differs from the prevalence in the general population. Regardless, there is increasing evidence that subclinical hypothyroidism represents an increase in the vulnerability to depression and may also make patients more refractory to standard antidepressant therapies. Furthermore, if subclinical hypothyroidism is identified in a patient with depression, it is still a matter of controversy whether the depression in fact represents a clinical manifestation of the endocrine abnormality and, therefore, necessitates replacement therapy with thyroid hormone. Although the use of thyroid replacement therapy in subclinical hypothyroidism requires further study, the presence of treatment refractoriness may justify the use of thyroid hormones in order to enhance the response to antidepressants and, therefore, reduce the risk of chronicity and/or recurrence that are commonly associated with a major depressive illness.

Thyroid in Psychiatric Illness

As noted previously, the vast majority of patients with depression are euthyroid and have no evidence of thyroid dysfunction. Clinical hypothyroidism is extremely rare in major depressive illness, although 5–10% of patients with major depression have evidence of subclinical hypothyroidism. In fact, in the majority of patients with primary major depression, there is evidence of slight thyroid axis overactivity. It is suggested that primary major depression may be associated with a stimulation of TRH, which in turn leads to increased release of TSH and, therefore, stimulates the thyroid gland to produce more T_4 and T_3 . The most common alterations of thyroid function seen in primary major depression are slight elevations in measures of T_4 , normal circulating levels of T_3 , and blunted TSH responses to TRH. These alterations of thyroid function tests are suggestive of TRH stimulation. Although these alterations of thyroid function

tests are seen when groups of depressed patients are compared to either psychiatric or healthy controls, thyroid hormone levels in depressed patients are usually within normal limits.

Despite the fact that thyroid function is rarely decreased in depressed patients and in fact may be relatively increased, there is a long-standing practice of using thyroid hormones to treat depressive illness. Thyroid hormones used alone have not shown particular efficacy in treating depressive disorders, but T_3 in particular has been shown to augment therapeutic response when added to the antidepressant regimen in patients who have had no or only a partial response to treatment. The limited evidence to date suggests that T_3 may be more effective than T_4 in this regard. Although this remains to be clarified in future studies, the convention has been to use T_3 instead of T_4 in such cases, in contrast to thyroid replacement therapy for clinical hypothyroidism in which T_4 instead of T_3 is the usual treatment. There is insufficient evidence for the efficacy of either TRH or TSH in the treatment of depression. Although T_3 is gaining increasingly widespread acceptance as a treatment for resistant depression, its mechanism of action is unknown. However, it appears clear that it is not used to correct either clinical or subclinical hypothyroidism in the majority of cases.

Definition and Historical Background
Treatment of Hysteria-Related Syndromes

Glossary

<i>Conversion disorder</i>	A psychiatric syndrome characterized by disturbances of bodily functions that do not correspond to known pathophysiological mechanisms.
<i>Dissociation</i>	The splitting of consciousness in an effort to repress painful memories; may result in either physical symptoms (somatization or conversion disorder), unconscious creation of alternative identities (multiple personality disorder), or inability to remain focused on present reality (borderline personality disorder).
<i>Free association</i>	A technique designed to uncover unconscious feelings. The patient lies down or sits comfortably and says anything that comes into his or her mind. Neither the patient nor the therapist makes any attempt to censor the thoughts, but the therapist listens and then interprets the associations.
<i>Repression</i>	Forgetting painful or frightening experiences. Repression is not a conscious process but, rather, an unconscious one; that is, the patient does not know that he or she has forgotten an event.
<i>Somatization disorder</i>	A psychiatric disorder in which the patient has many somatic complaints, but no underlying medical problem can be identified.

Definition and Historical Background

Clinical Vignettes

Patient 1 S.M. was 21 years old and in good health until she was out with her fiancé and he was hit by a swerving cab as he tried to push S.M. to safety. He died 3 days later. S.M. awakened on the day of the funeral to discover that she could not walk. She reported that she was paralyzed and could not walk or sit up. Her family tried to help her out of bed, and she simply collapsed. Her parents were quite upset, but she seemed relatively calm and told them it did not matter. She urged them to go to the funeral for her because she could not move. They consulted a prominent neurologist who could not find any abnormalities.

Patient 2 G.H. was 27 years old and sought treatment from a urologist for pain on urination and difficulty initiating urination. The urologist examined her and noted a urethral stricture that he treated with good success. Six weeks later, however, the patient called and said she was having pain in her pelvic area. He reexamined her, but could find nothing. The urologist suggested she consult her gynecologist, which she did. The gynecologist could not find any problem, but gave the patient some exercises to do to strengthen her pelvic muscles. The pain gradually subsided. However, the patient called 3 months later because of difficulties with her “bowels and stomach.” The gynecologist referred her to a gastroenterologist who did a complete workup, but could not find any abnormalities. During the evaluation, G.H. did tell the gastroenterologist that she had recently begun her first sexual relationship and was having a great deal of difficulty with this. The gastroenterologist referred her to a psychiatrist, who worked with G.H. for several months before she finally elicited a history of severe and repeated sexual abuse that had occurred during childhood. This abuse had produced

the urethral stricture and was now causing sexual and psychological difficulties for the patient as she tried to function in a normal adult romantic relationship.

Historical Changes in the Meaning of Hysteria

The word hysteria is familiar to most clinicians and lay people, but is elusive in definition. It is no longer used in psychiatric or psychological nomenclature, but, surprisingly, it was once the cornerstone of modern psychiatry. Several scholars of the history of psychiatry have proposed that the epidemic of hysteria afflicting American and British women in the late nineteenth and early twentieth centuries spawned the field of psychoanalysis. However, the disorder has now virtually disappeared. Furthermore, the term hysteria, once the focus of intensive treatment efforts and research, can scarcely be found in modern mainstream psychiatric literature.

The symptoms of hysteria can be found as early as 1900 BC in the Egyptian papyri (the actual word hysteria is derived from *hystera*, Greek for uterus). In both Egyptian and Greek writings, this multisymptom complex described in women was thought to be caused by a wandering uterus. Treatments were directed at coaxing the uterus to return to the pelvis and keeping it there once it returned. Assuming that sexual intercourse and childbirth would keep the uterus from moving, the most common prescription was for marriage and coitus.

Subsequent centuries brought changes in the definition and hypothesized etiology of hysteria. The definition became quite broad, referring to nearly any symptom of disease that was found more often in women than in men. Etiological explanations continued to focus on uterine pathology but also included causes such as satanic possession.

The nineteenth century brought a dramatic increase in the incidence of hysteria, although it is not clear why this happened. Treatments continued to focus on the uterus and newly discovered ovaries. The cauterization of the cervix, leeches applied to the cervix and vagina, and the removal of the ovaries were all common treatments that were only moderately successful. In the late nineteenth century, however, hypnosis was discovered to be useful for curing some symptoms of hysteria, such as the paralysis described earlier in S.M. Janet, Freud, and others believed that the mechanism of this cure was that hypnosis allowed the therapist, and then later the patient, to gain access to repressed feelings. In exploring these hidden feelings, buried conflicts could be resolved and the symptoms would disappear. The use of hypnosis diminished as Freud developed the technique of free association with interpretation by

the analyst. This technique became the hallmark of psychoanalysis and was eventually used for many psychiatric disorders.

The *Diagnostic and Statistical Manual* 4th edn. (DSM-IV) has reclassified hysteria into two other disorders in the somatoform disorders category: conversion disorder (CD) and somatization disorder (SD). CD is a psychiatric syndrome characterized by disturbances of bodily functions (e.g., blindness, hearing loss, paralysis, and lack of sensation) that do not correspond to known pathophysiological mechanisms. SD is a psychiatric disorder in which the patient has many different somatic complaints but no underlying medical problem can be identified.

As with hysteria, these disorders are more common in women. However, we now know from clinical and research data on combat and natural disasters that men may also present with unusual physical symptoms that do not have medical explanations. The primary risk factor for both disorders in men and women is trauma or extremely stressful events over which the patient has no control. The trauma may be acute, as in the case of S.M. or exposure to battle, or chronic and repressed, as in the case of G.H., who had been the victim of repeated sexual abuse. She had remained asymptomatic until her first sexual relationship reawakened bodily sensations associated with a time of great stress earlier in her life.

Overwhelming stress in the context of helplessness seems to be the key feature of situations that produce SD or CD. However, studies of the function of either the sympathoadrenal or hypothalamic-pituitary-adrenal (HPA) axis components of the stress-response system have not demonstrated consistent abnormalities. It does appear that patient with SD are more subjectively sensitive to pain, with greater stress-response system reactivity. The multiple illnesses in SD may be due to a sensitization of the brain cytokine system by past adverse experiences such that it responds with a sickness pattern to a lower threshold of stress than is usually required in other people.

Treatment of Hysteria-Related Syndromes

Conversion Disorder

A complete medical and psychiatric workup is essential to rule out any medical pathology that merits treatment. In some cases, even an acute trauma is not known to the physician or psychologist (e.g., rape or an abortion of a hidden pregnancy). In this case, repressed trauma can sometimes be discovered with an interview that takes place when the patient is

under the influence of amobarbital or lorazepam. On occasion, hypnosis is still used. The symptoms of a CD remit spontaneously in the majority of cases. The establishment of a nonjudgmental therapeutic relationship seems crucial for the treatment of patients whose symptoms do not subside quickly. With this type of a relationship, the exploration of latent trauma can be accomplished and healthier ways to cope with stress can be taught.

Somatization Disorder

As with CD, patients with suspected SD should receive complete medical workups. The primary danger in treating this disorder is that the patient can receive many invasive evaluations that are both expensive and disruptive to her life before someone notices the pattern of multiple, changing somatic complaints. There are three strategies for treating this disorder. The first is to control the frequent doctor shopping. This is accomplished most often by establishing a single physician to manage all aspects of care. This person keeps track of all medical care and schedules frequent contact with the patient. Second, some patients have had a positive response to antidepressant medication. The final treatment strategy is psychotherapy, focusing on any early trauma and the effect it may have on the patient's current ability to cope with stress. The prognosis for SD is not good unless the patient responds to an antidepressant or is motivated to embark on a course of psychotherapy.

Summary and Conclusion

Glossary

Immobilization A model of stress that has been employed in studies of laboratory rats and mice. The procedure involves taping the four limbs of a rat or mouse to mounts secured to a metal frame using hypoallergenic tape. A pair of metal loops attached to the frame limits the range of motion of the animal's head. The frame, loops, and mounts are fabricated of stainless steel. The duration of a single episode of immobilization usually varies from 5 to 120 min or more. In addition, animals in chronic stress protocols may be immobilized each day for many weeks even months.

Restraint A model of stress whereby laboratory rats or mice are restricted in their range of movement. Each animal is secured in a plastic tube or a wire-mesh container that is small enough to prevent the animal from moving about or turning. The

frequency and duration of restraint stress vary depending on the questions being addressed by a given study, but a permanent restraint could last for many weeks.

Immobilization was introduced as a model of stress in animal experimentation in the mid-1960s. Since that time, Kvetnansky and colleagues have developed a standard protocol for immobilizing laboratory rats that involves securing the four limbs of a rat to mounts on a metal frame with hypoallergenic tape. The range of motion of an animal's head is limited by rings that are fixed to the metal frame. An acute episode of immobilization typically lasts from 5 to 120 min. In addition, animals can be immobilized daily (usually for 120 min) for many weeks to study the biological effects of adaptation to repeated immobilization stress.

During the first exposure to immobilization stress, laboratory rats or mice typically struggle vigorously to free themselves for 20–30 min. After that time, they will often cease struggling and remain motionless until a disturbance occurs. When one animal begins to struggle or if there is a sudden loud noise or some other form of sensory stimulation, many of the animals in the group that is being immobilized will begin to struggle again. Animals that have been immobilized daily for many days display signs of habituation to the stressor and calm down much sooner than naïve animals being immobilized for the first time.

Immobilization is a complex stressor and includes physical as well as psychological dimensions. The struggling and associated muscular exertion that occur during immobilization represent an intense form of physical exercise. After the first immobilization exposure, animals are so exhausted that they hardly move. In addition, the limited range of movement and exposure in an open area are significant sources of psychological stress to laboratory animals. It is also

quite common for repeatedly immobilized adult rats to lose a significant amount of body weight over a 1- to 4-week period as a result of an increase in physical training and a decrease in food intake. After that period, repeatedly immobilized animals begin to gain weight at a rate that is similar to unstressed controls. However, the absolute body weights of stressed rats remain below those of control rats.

Variations in Immobilization

Since its introduction as a laboratory stressor, immobilization has been modified and adapted for the unique needs of different laboratories. Unfortunately, it is all too easy to assume that all models of stress involving immobilization are the same. In fact, it is very difficult to compare studies unless the technique for immobilization is comparable. For example, many investigators have used restraint as a model of stress. Restraint may involve placing the test animal into a plastic tube or a wire-mesh container that is well ventilated. Although the animal's range of movement is severely limited, the limbs are not secured and the animal remains within an enclosed area. Many have argued that restraint stress is less intense a stressor than immobilization, and comparative studies using neural and endocrine measures have supported this assertion.

Immobilization may also be combined with other stressors, such as cold temperatures or even placing the immobilization board in shallow water such that the animal is partially submerged. Caution should be exercised in comparing such studies with others because the addition of a second stressor affects an animal's physiological and behavioral responses.

Immobilization has also been employed in the development of an animal model of long-term weightlessness. This model involves the continuous restriction of movement of laboratory rats for as long as 60 days to simulate some of the physiological changes that attend long-term space flight. The hypokinesia apparatus is modified such that the animal can gain access to food and water. It bears some similarity to studies with humans that have included long-term bed rest as a model of weightlessness associated with space flight.

Advantages and Disadvantages

Without doubt, immobilization has evolved into one of the most frequently employed models of stress in studies with laboratory rats and, recently, mice. There are several reasons for this. No special equipment is required other than the immobilization boards, which can be fabricated of stainless steel in a departmental

or institute shop and used for many years (the authors have used the same boards for more than 30 years). Once the animals have been immobilized, the investigator is free to do other things in the laboratory until the end of the stress session for that day. In addition, the stressor is sufficiently intense such that most stress-responsive biological systems are altered and their regulatory processes may be studied ([Tables 1 and 2](#)). Immobilization is well tolerated by laboratory rats and mice and can be used in studies of chronic intermittent stress over weeks or even months. Finally, there is extensive literature on biological responses to immobilization that may be consulted when an investigator is planning an experiment that involves using an acute or a repeated stressor.

The immobilization model of stress does have its limitations, however. The intensity of the stressor cannot be altered, as we can do with foot-shock stress or cold stress, for example. In addition, measures of behavioral responses to immobilization stress are not usually an element of the experimental protocols. This limits the use of this model of stress when investigators have a specific interest in relating physiological and behavioral responses to the same stressful stimulus.

Acute versus Chronic Immobilization

Immobilization stress has provided an especially useful model for exploring the molecular and physiological adaptations that occur when animals are exposed to a regimen of chronic daily stress. Although immobilization is an intense stressor, considerable evidence shows that many neural and endocrine systems do exhibit decreases in the magnitude of their responses following repeated daily bouts of immobilization stress. These habituated responses are also characteristic of other laboratory stressors (e.g., restraint, foot shock, swim stress, handling, and open field testing) that are less intense than immobilization.

In laboratory rats that are exposed to repeated daily episodes of immobilization stress, there is an enhanced response of many neural and endocrine systems if the same animals are exposed to a novel stressor. The proper control group to demonstrate this sensitization effect is a group of naïve control rats with no prior history of experimenter-controlled stress that is exposed to the novel stressor for the first time.

Immobilization-Induced Gene Expression

In studies of transcriptional regulation of genes involved in neurotransmitter and hormone biosynthesis, immobilization has served as a valuable stress

Table 1 Selected neurochemical and neurohumoral responses of laboratory rats to acute immobilization stress^a

Variable	Baseline	Stress	Peak time (min)
<i>Norepinephrine</i>			
Adrenal content (μg/adrenal)	3.2 ± 0.2	2.0 ± 0.3	120
Urine levels (μg/kg/24 h)	1.8 ± 0.2	4.9 ± 0.3	30
Plasma levels (pmol/ml)	1.25 ± 0.3	7.3 ± 1.2	20
<i>Epinephrine</i>			
Adrenal content (μg/adrenal)	17.5 ± 0.6	14.6 ± 0.4	120
Urine levels (μg/kg/24 h)	0.8 ± 0.06	2.6 ± 0.4	120
Plasma levels (pmol/ml)	0.20 ± 0.03	15.5 ± 2.7	5
<i>Plasma levels of:</i>			
DOPA (pmol/ml)	3.3 ± 0.2	3.9 ± 0.4	5
Dopamine (pmol/ml)	0.8 ± 0.09	1.25 ± 0.4	20
Dihydroxyphenylglycol (pmol/ml)	3.2 ± 0.3	9.3 ± 1.0	20
Methoxyhydroxyphenylglycol (pmol/ml)	15 ± 2.0	62 ± 15	60
Dihydroxyphenylacetic acid (pmol/ml)	5.2 ± 0.6	13.5 ± 0.2	20
Homovanillic acid (pmol/ml)	22 ± 4	55 ± 6	20
Plasma acetylcholinesterase (nmol/min/ml)	71 ± 5	112 ± 8	120
Plasma renin activity (ng/min/h)	4.4 ± 0.9	29.3 ± 4.7	10
Plasma aldosterone (pg/ml)	970 ± 90	3190 ± 460	120
Vasopressin (fmol/ml)	1.9 ± 0.2	6.1 ± 2.3	2
ACTH (pg/ml)	44 ± 4	790 ± 225	30
Corticosterone (μg/100 ml)	3.9 ± 0.2	24.5 ± 2.7	120
Prolactin (ng/ml)	7.2 ± 0.5	71 ± 17	20
<i>Microdialysate norepinephrine (pg/ml)</i>			
Paraventricular nucleus	178 ± 17	475 ± 37	30
Bed nucleus of the stria terminalis	92 ± 12	360 ± 38	30
Central nucleus of the amygdala	151 ± 8	425 ± 53	30

^aValues are means ± SEM. All data on plasma levels of various substances were obtained from chronically catheterized animals. All data on microdialysate norepinephrine levels were obtained from animals that were surgically prepared with chronic microdialysis probes. All values are estimates of data presented in figures of published papers that employed immobilization stress in studies using laboratory rats.

Table 2 Quantitative changes in gene expression of catecholamine biosynthetic enzymes during acute immobilization stress^a

Variable	Baseline	Stress	Peak time (h)
Adrenal medulla			
TH mRNA (amol/ng RNA)	0.46 ± 0.06	3.10 ± 0.56	3 after IMMO
DBH mRNA (amol/ng RNA)	6.00 ± 0.84	15.20 ± 1.57	3 after IMMO
PNMT mRNA (amol/ng RNA)	28.00 ± 2.36	141.0 ± 20.8	3 after IMMO
Stellate ganglia			
TH mRNA (amol/ng RNA)	0.017 ± 0.002	0.038 ± 0.005	24 after IMMO
DBH mRNA (amol/ng RNA)	2.60 ± 0.20	6.45 ± 0.61	24 after IMMO
PNMT mRNA	Present; not enough for quantification		
Brain stem			
TH mRNA (amol/μgRNA)			
Locus coeruleus	75.0 ± 8.7	268.0 ± 34.0	24 after IMMO
NTS (A2)	4.6 ± 1.0	9.6 ± 1.1	24 after IMMO
A1 area	17.0 ± 2.0	109.0 ± 11.0	3 after IMMO
Hypothalamus			
TH mRNA (amol/μg RNA)			
Paraventricular n.	5.2 ± 0.6	14.0 ± 1.8	3 after IMMO
Supraoptic n.	3.1 ± 0.9	10.4 ± 2.0	24 after IMMO
Dorsomedial n.	0.8 ± 0.1	5.5 ± 1.3	24 after IMMO
Arcuate n., lateral	8.0 ± 1.4	12.0 ± 0.6	24 after IMMO
Arcuate n., medial	11.0 ± 2.3	18.0 ± 2.5	3 after IMMO

^aValues are means ± SEM. Values are from data presented in figures of published papers that employed immobilization stress in rats. DBH, dopamine-B-hydroxylase; IMMO, immobilization; n., nucleus; PNMT, phenylethanolamine N-methyltransferase; TH, tyrosine hydroxylase.

model. Kvetnansky, Sabban, Wong, and co-workers have examined changes in the transcription rates of genes for enzymes involved in catecholamine biosynthesis in central and peripheral tissues. These include genes for tyrosine hydroxylase (TH), dopamine- β -hydroxylase (DBH), and phenylethanolamine-N-methyltransferase (PNMT) (Table 2). For example, their work has shown that adrenal medullary TH mRNA concentration (expressed in amol ng⁻¹ total RNA) increase approximately sixfold above control levels following a single 2-h period of immobilization. This increase is transient and levels of TH mRNA return to control levels within 24 h. However, if rats are immobilized for 2 h per day for 2–7 consecutive days, TH mRNA levels increase as much as sixfold above basal levels and these elevated levels are maintained up to 24 h later. The concentrations of DBH and PNMT mRNA in the adrenal medulla are 15–70 times higher, but are further elevated during immobilization stress. These increases are transient and within 24 h return to control levels. TH and DBH mRNA concentrations in the sympathetic ganglia show lower levels than those in the adrenal medulla. During immobilization, the ganglionic mRNA levels are significantly elevated; however, they stay increased even 24 h after the end of immobilization.

PNMT mRNA is also present in sympathetic ganglia in a very low concentration. PNMT gene expression has also been detected in other peripheral tissues such as the heart atria and ventricles, spleen, and thymus, and immobilization stress induced a many-fold increase of PNMT mRNA levels in these tissues.

TH mRNA levels also increase significantly within catecholaminergic cell bodies of the brain-stem areas, for example, the nucleus locus coeruleus, nucleus tractus solitarius, and A1 area, and in some hypothalamic nuclei following immobilization stress (Table 2). In these hypothalamic areas, catecholaminergic cells were not originally described.

The expression of genes that encode catecholamine biosynthetic enzymes is mediated by transcriptional mechanisms. Recent work identified various transcription factors that are associated with the brief or intermediate duration of a single or repeated immobilization stress exposure. It has been shown that the genes coding for the catecholamine biosynthetic enzymes contain several regulatory genomic elements in their promoters, for example, the cAMP response element (CRE), glucocorticoid response element (GRE), activating enhancer binding protein (AP)-1, AP-2, POU/Oct, and SP1 sites. The signaling molecules that may influence the transcription rates of the genes for TH, DBH, and PNMT, include P-cAMP response element binding protein (CREB), Jun N-terminal kinase (JNK), c-fos, Egr-1, Fra-1, and Fra-2.

With repeated daily stress exposure, Fra-2 was a major AP-1 factor induced in the adrenal medulla, but Egr-1 levels were also markedly elevated.

For PNMT gene expression, two transcription factors are important especially: glucocorticoid receptor and Egr-1. The crucial role of glucocorticoids in PNMT gene regulation has also been confirmed in corticotropin releasing hormone (CRH) (corticoliberin) knockout mice exposed to immobilization.

The signaling pathways triggered by immobilization differ in different tissues. In the adrenal medulla, immobilization triggered activation of the mitogen-activated protein kinase (MAPK), JNK, and induction of AP-1 factors, Egr-1 and phosphorylation of CREB. In contrast, in the sympathetic ganglia of immobilized animals were not observed changes in JNK and only little binding to the AP-1 motif of the TH promoter. However, there was an increase in CREB binding to the CRE site of the TH promoter. A single episode of immobilization also triggered the elevation of c-fos in the brain areas, especially in the locus coeruleus. In this area, increased phosphorylation of CREB was also observed after both single and repeated immobilization; however, the levels of Fra-2 and Egr-1 were not changed (in the adrenal medulla these transcription factors were highly activated). These results reveal differential mechanisms of regulation of gene expression of catecholamine biosynthetic enzymes by immobilization stress in two components of the sympathoadrenal system (adrenal medulla and sympathetic ganglia) as well as in the brain areas.

These findings related to the gene expression of catecholamine biosynthetic enzymes provide an excellent example of how immobilization has been useful in tracking the regulation of gene transcription during acute and chronic stress. In addition, these findings on gene expression may be compared with similar studies relating to the regulation of other genes because immobilization stress has been adopted as a model in a host of different laboratories.

Inventory of Neurohumoral and Genetic Responses to Acute Immobilization

Tables 1 and 2 present an abbreviated summary of biological responses of laboratory rats to a single 2-h period of immobilization stress. Table 1 emphasizes the responses of the sympathetic nervous system, the adrenal medulla, and the hypothalamic-pituitary-adrenocortical system because of the importance of these systems in contemporary stress research. Table 2 emphasizes changes in gene expression of catecholamine biosynthetic enzymes during the exposure of rats to an acute immobilization stress. This archival information was obtained from many

journal articles (see Further Reading for secondary reference sources). This information provides a useful inventory with which we may compare the responses of the same biological systems to other types of laboratory stressors.

Summary and Conclusion

Since the mid-1960s, immobilization has become one of the most frequently employed laboratory models of stress. The protocols for acute and chronic immobilization have been described clearly, and many laboratories have incorporated this procedure into their studies of stress. A rich and varied literature is available on biological responses to immobilization, and these findings have provided important insights into the molecular, genetic, endocrine, and neural adaptations that occur in laboratory rats following acute versus chronic stress.

Stress-Induced Redistribution of Blood Leukocytes
Conclusion

Glossary

B lymphocytes The antibody-producing cells of the body, originating in the bone marrow. B lymphocytes are also identified by the surface expression of specific molecules such as CD19.

Introduction

Stress

The Immune System

Stress-Induced Changes in Blood Leukocytes

Hormones Mediating a Stress-Induced Decrease in Blood Leukocytes

<i>Fluorescence-activated cell sorter (FACS)</i>	An instrument used to rapidly quantify the relative percentages of different cell types in a cell suspension. The identification of different cells is achieved based on the size, granularity, and fluorescence properties of the cell. Fluorescence is derived from fluorescently conjugated antibodies that bind specific markers on the cell surface.
<i>Immune response</i>	A reaction mounted by various components of the immune system, which consists of leukocytes, antibodies, cytokines and chemokines (messenger molecules), prostaglandins (inflammatory mediators), and accessory cells.
<i>Leukocytes</i>	Cells that constitute the immune system. These include T and B lymphocytes, natural killer (NK) cells, monocytes/macrophages, and granulocytes.
<i>Lymphocytes</i>	Leukocytes that specifically recognize and respond to foreign antigen.
<i>Monocytes/macrophages</i>	Cells that phagocytose foreign particles and self tissues that are injured (monocytes generally flow through the blood and mature into macrophages after they are activated and extravasate into tissues). They produce cytokines, which recruit other leukocytes to the site of an immune response, and they perform an important function known as antigen presentation, which is crucial to the initiation of specific immune responses by lymphocytes. Also known as mononuclear phagocytes.
<i>Natural killer (NK) cells</i>	Large granular lymphocytes that lyse virally infected cells and tumors in the absence of specific antigenic stimulation. They are identified by surface molecules such as CD16 and CD56.
<i>Neutrophils</i>	Cells that perform functions similar to mononuclear phagocytes and that form an important component of an acute inflammatory response; also known as polymorphonuclear leukocytes.
<i>T lymphocytes</i>	Leukocytes that are mediators of cellular immunity. Like all leukocytes, they are formed in the bone marrow but mature in the thymus. Helper T lymphocytes (Ths) orchestrate immune responses by secreting cytokines and recruiting other leukocytes to the site of an immune reaction and activating them at that site; most Th cells express a surface protein called CD4, which is used to identify them. Cytolytic T lymphocytes (CTLs) lyse cells that are infected by intracellular viruses or bacteria; most CTLs express a surface protein called CD8, which is used to identify them.

Introduction

Effective immunoprotection requires the rapid recruitment of leukocytes into sites of surgery, wounding, infection, or vaccination. Immune cells or leukocytes circulate continuously on surveillance pathways taking them from the blood, into various organs, and back into the blood. This circulation is essential for the maintenance of an effective immune defense network. The numbers and proportions of leukocytes in the blood provide an important representation of the state of distribution of leukocytes in the body and of the state of activation of the immune system. Numerous studies have shown that stress and stress hormones induce significant changes in absolute numbers and relative proportions of leukocytes in the blood.

Dhabhar et al. were the first to propose that a stress-induced decrease in blood leukocyte numbers may represent an adaptive response. These investigators suggested that acute stress-induced changes in blood leukocyte numbers represent a redistribution of leukocytes from the blood to other organs, such as the skin and lining of the gastrointestinal and urinary-genital tracts and their draining lymph nodes. They also suggested that such a leukocyte redistribution may enhance immune function in those compartments to which leukocytes traffic during stress. In agreement with this hypothesis, it has been demonstrated that a stress-induced redistribution of leukocytes from the blood to the skin is accompanied by a significant enhancement of a skin immune response. Here we discuss stress- and stress hormone-induced changes in blood leukocyte distribution and investigate the functional consequences of a stress-induced redistribution of blood leukocytes.

Stress

Although the word stress generally has negative connotations, stress is a familiar aspect of life, being a stimulant for some but a burden for others. Numerous definitions have been proposed for the word stress. Each definition focuses on aspects of an internal or external challenge, disturbance, or stimulus; on the perception of a stimulus by an organism; or on a physiological response of the organism to the stimulus. Physical stressors have been defined as external challenges to homeostasis, and psychological stressors have been defined as the "anticipation justified or not, that a challenge to homeostasis looms." (Sapolsky, 2005, p. 648). An integrated definition states that stress is a constellation of events, consisting of a stimulus (stressor) that precipitates a reaction in the brain (stress perception), which activates

physiological fight-or-flight systems in the body (stress response). The physiological stress response results in the release of neurotransmitters and hormones that serve as the brain's messengers to the rest of the body. This article examines the role played by stress and stress hormones in enhancing different aspects of an immune response. It is often overlooked that a stress response has salubrious adaptive effects in the short run, although stress can be harmful when it lasts a long time. An important distinguishing characteristic of stress is its duration and intensity. Thus, we define acute stress as stress that lasts for a period of a few minutes to a few hours and chronic stress as stress that persists for several hours per day for weeks or months. The intensity of stress may be gauged by the peak levels of stress hormones, neurotransmitters, by other physiological changes such as increases in heart rate and blood pressure, and by the amount of time for which these changes persist during stress and following the cessation of stress.

The Immune System

Immune Cells and Organs

The immune system consists of organs (bone marrow, spleen, thymus, and lymph nodes), cells (T cells; B cells; natural killer, NK, cells; monocytes/macrophages; and neutrophils), and messenger molecules (cytokines, chemokines, and prostaglandins). These components of the immune system are spread throughout the body and are in constant communication with one another. The appropriate distribution of immune cells in the body is crucial to the performance of the different functions of the immune system.

Functions of the Immune System

The functions of the immune system may be classified into six major categories:

1. Constant surveillance of the body in preparation for potential immunological challenges (such as those described in the other five categories).
2. Detection and elimination of infectious agents such as bacteria, viruses, fungi, and other microorganisms and parasites from the body.
3. Detection and elimination of noninfectious foreign matter from the body.
4. Wound repair and healing.
5. Clearance of debris that may result from noninjurious events such as programmed cell death (apoptosis) in host tissues.
6. Detection and elimination of tumors and neoplastic tissue.

Thus, the immune system may be regarded as the body's army with soldiers (immune cells) moving from their barracks (bone marrow, lymph nodes, spleen, and thymus) through highways (blood vessels and lymphatic ducts) and patrolling almost all organs within the body, especially those organs (skin, lining of gastrointestinal and urinary-genital tracts, lung, liver, lymph nodes, and spleen) that may serve as potential battle stations should the body's defenses be breached. In order to perform their functions, immune cells communicate with one another and with the rest of the body through messenger molecules such as cytokines and chemokines.

Immune Cell Trafficking

The appropriate distribution of immune cells between different tissues in the body is crucial to the performance of the immune functions. Leukocyte trafficking is the process by which leukocytes circulate between immune and nonimmune organs as they patrol the body and discharge their functions. Leukocyte trafficking is accomplished through interactions between adhesion molecules on leukocytes and endothelial cells that ultimately determine the location of immune cells within the body. The three major families of adhesion molecules are the selectins, the immunoglobulin superfamily, and the integrins. Adhesion molecules mediate three important steps (rolling, anchoring, and extravasation) that are involved in capturing leukocytes from the circulation. For example, a T cell flowing through the bloodstream may be selectively retained within the vasculature of the skin if a particular adhesion molecule is expressed on the T cell and its corresponding ligand is expressed on skin endothelial cells. Thus, hormones, cytokines, and chemokines may influence the location of leukocytes in the body by regulating the conformation or expression of adhesion molecules and/or their ligands on leukocytes and endothelial cells.

The Immune Response

It is important to note that, although immune reactions are classified into different categories (e.g., innate, acquired, cell-mediated, or humoral reactions), an immune response is often a combination of different immune reactions. The immune response protects the body from infections, wounds, and tumors. Although mechanisms for self- and counterregulation exist between various immune components, mechanisms also exist by which immune responses may be modulated or influenced by mediators such as hormones and neurotransmitters. Stress, and its consequent release of hormones and neurotransmitters, has

been shown to influence specific immune parameters such as leukocyte trafficking, NK cell activity, lymphocyte proliferation, antibody production, effector cell function, and cell-mediated immune reactions.

Stress-Induced Changes in Blood Leukocytes

The phenomenon of acute stress-induced changes in blood leukocyte numbers is well known. In fact, decreases in blood leukocyte numbers were used as an indirect measure for increases in plasma corticosterone before methods were available to directly assay the hormone. Stress-induced changes in blood leukocyte numbers have been reported in fish, mice, rats, rabbits, horses, nonhuman primates, and humans. This suggests that the phenomenon of stress-induced leukocyte distribution has a long evolutionary lineage and that perhaps it has functional significance.

Many of these studies have shown that stress-induced increases in plasma corticosterone are accompanied by a significant decrease in numbers and percentages of lymphocytes and by an increase in numbers and percentages of neutrophils. FACS analyses have revealed that absolute numbers of peripheral blood T cells, B cells, NK cells, and monocytes all show a rapid and significant decrease (40–70% lower than baseline) during stress. These stress-induced changes in leukocyte numbers are rapidly reversed on the cessation of stress.

Hormones Mediating a Stress-Induced Decrease in Blood Leukocytes

Several studies have examined stress hormone-induced changes in blood leukocyte numbers. It has been shown in rats that both adrenalectomy (which eliminates the corticosterone and epinephrine stress response) and cyanoketone treatment (which eliminates only the corticosterone stress response) virtually eliminate the stress-induced redistribution of blood leukocytes. Studies have also shown that adrenal steroid and catecholamine hormones mediate the stress-induced changes in blood leukocyte numbers and that glucocorticoid treatment induces changes in leukocyte distribution in mice, guinea pigs, rats, and humans. These studies clearly show that glucocorticoid hormones induce a significant decrease in blood lymphocyte numbers when administered under acute as well as chronic conditions. Similarly studies have delineated the importance of catecholamine hormones in mediating stress-induced changes in blood leukocyte distribution in rodents and humans.

A Stress-Induced Decrease in Blood Leukocyte Numbers Represents a Redistribution Rather than a Destruction or Net Loss of Blood Leukocytes

From the discussion so far, it is clear that stress and glucocorticoid hormones induce a rapid and significant decrease in blood lymphocyte, monocyte, and NK cell numbers. This decrease in blood leukocyte numbers may be interpreted in two possible ways. The decrease in cell numbers could reflect a large-scale destruction of circulating leukocytes. Alternatively, it could reflect a redistribution of leukocytes from the blood to other organs in the body. Experiments were conducted to test the hypothesis that acute stress induces a redistribution of leukocytes from the blood to other compartments in the body.

The first series of experiments examined the kinetics of recovery of the stress-induced reduction in blood leukocyte numbers. It was hypothesized that if the observed effects of stress represented a redistribution rather than a destruction of leukocytes, we would see a relatively rapid return of leukocyte numbers back to baseline on the cessation of stress. Results showed that all leukocyte subpopulations that showed a decrease in absolute numbers during stress showed a complete recovery, with their numbers reaching pre-stress baseline levels within 3 h after the cessation of stress. Plasma levels of lactate dehydrogenase (LDH), which is a marker for cell damage, were also monitored in the same experiment. If the stress-induced decrease in leukocyte numbers were the result of a destruction of leukocytes, we would expect to observe an increase in plasma levels of LDH during or following stress. However, no significant changes in plasma LDH were observed, further suggesting that a redistribution rather than a destruction of leukocytes was primarily responsible for the stress-induced decrease in blood leukocyte numbers.

It is important to bear in mind that, although glucocorticoids are known to induce leukocyte apoptosis under certain conditions, they have also been shown to induce changes in various immune parameters and in immune cell distribution in the absence of cell death. It has been suggested that some species may be steroid-resistant and that others may be steroid-sensitive and that glucocorticoid-induced changes in blood leukocyte numbers represent changes in leukocyte redistribution in steroid-resistant species (humans and guinea pigs) and leukocyte lysis in steroid-sensitive species (mouse and rat). However, it is now accepted that, even in species previously thought to be steroid-sensitive, changes in adrenal

steroids similar to those described here produce changes in leukocyte distribution rather than an increase in leukocyte destruction.

Target Organs of a Stress-Induced Redistribution of Blood Leukocytes

Based on this discussion, the obvious question we might ask is: Where do blood leukocytes go during stress? Numerous studies using stress or stress hormone treatments have investigated this issue. Using gamma imaging to follow the distribution of adoptively transferred radiolabeled leukocytes in whole animals, experiments showed that stress induces a redistribution of leukocytes from the blood to the mesenteric lymph nodes. It has been reported that anesthesia stress, as well as the infusion of adrenocorticotrophic hormone (ACTH) and prednisolone in rats results in decreased numbers of labeled lymphocytes in the thoracic duct, whereas the cessation of drug infusion results in the normal circulation of labeled lymphocytes. This suggests that ACTH and prednisolone (which produce hormonal changes similar to those observed during stress) may cause the retention of circulating lymphocytes in different body compartments, thus resulting in a decrease in lymphocyte numbers in the thoracic duct and a concomitant decrease in numbers in the peripheral blood. It has also been reported that a single injection of hydrocortisone, prednisolone, or ACTH results in increased numbers of lymphocytes in the bone marrow of mice, guinea pigs, and rats. Fauci et al. suggested that glucocorticoid-induced decreases in blood leukocyte numbers in humans may also reflect a redistribution of immune cells to other organs in the body. Finally, corticosteroids have been shown to induce the accumulation of lymphocytes in mucosal sites, and the skin has been identified as a target organ to which leukocytes traffic during stress. *In vitro* catecholamine treatment has also been shown to direct leukocyte traffic to the spleen and lymph nodes.

It is important to note that in these studies a return to basal glucocorticoid levels was followed by a return to basal blood lymphocyte numbers, further supporting the hypothesis that the decrease in blood leukocyte numbers is the result of a glucocorticoid-induced redistribution rather than a glucocorticoid-induced destruction of blood leukocytes. In view of this, Dhabhar et al. proposed that a transient stress-induced decrease in blood leukocyte numbers reflects a redistribution or redeployment of leukocytes from the blood to other organs (e.g., lymph nodes, bone marrow, and skin) in the body.

Stress-Induced Redistribution of Blood Leukocytes

Molecular Mechanisms

It is likely that the observed changes in leukocyte distribution are mediated by changes in either the expression or affinity of adhesion molecules on leukocytes and/or endothelial cells. It has been suggested that following stress or glucocorticoid-treatment specific leukocyte subpopulations (being transported by blood and lymph through various body compartments) may be selectively retained in those compartments in which they encounter a stress- or glucocorticoid-induced adhesion match. As a result of this selective retention, the proportion of some leukocyte subpopulations would decrease in the blood and increase in the organ in which they are retained (e.g., the skin).

Support for this hypothesis comes from studies that show that acute psychological stressors such as public speaking can induce significant changes in leukocyte adhesion molecules. Prednisolone has also been shown to induce the retention of circulating lymphocytes within the bone marrow, spleen, and some lymph nodes, thus resulting in a decrease in lymphocyte numbers in the thoracic duct and a concomitant decrease in numbers in the peripheral blood. Moreover, glucocorticoid hormones also influence the production of cytokines and lipocortins that, in turn, can affect the surface adhesion properties of leukocytes and endothelial cells. Further investigation of the effects of endogenous glucocorticoids (administered in physiological doses, and examined under physiological kinetic conditions) on changes in the expression/activity of cell surface adhesion molecules and on leukocyte-endothelial cell adhesion is necessary.

Functional Consequences

It had been proposed that a stress-induced decrease in blood leukocyte numbers may represent an adaptive response, that is, a redistribution of leukocytes from the blood to other organs such as the skin, lining of gastrointestinal and urinary-genital tracts, lung, liver, and lymph nodes that may serve as potential battle stations should the body's defenses be breached. It has been suggested that such a leukocyte redistribution may enhance the immune function in those compartments to which leukocytes traffic during stress.

Thus, an acute stress response may direct the body's soldiers (leukocytes) to exit their barracks (the spleen and bone marrow), travel the boulevards (blood vessels), and take up position at potential battle stations (the skin, lining of gastrointestinal

and urinary-genital tracts, lung, liver, and lymph nodes) in preparation for an immune challenge. In addition to sending leukocytes to potential battle stations, stress hormones may also better equip them for battle by enhancing processes such as antigen presentation, phagocytosis, and antibody production. Thus, a hormonal alarm signal released by the brain on detecting a stressor, may prepare the immune system for potential challenges (wounding or infection) that may arise due to the actions of the stress-inducing agent (e.g., a predator or attacker).

When interpreting data showing stress-induced changes in functional assays such as lymphocyte proliferation or NK activity, it may be important to bear in mind the effects of stress on the leukocyte composition of the compartment in which an immune parameter is being measured. For example, it has been shown that acute stress induces a redistribution of leukocytes from the blood to the skin and that this redistribution is accompanied by a significant enhancement of a skin cell-mediated immune (CMI) response. In what might at first glance appear to be contradicting results, acute stress has been shown to suppress splenic and peripheral blood responses to T-cell mitogens and splenic IgM production. However, it is important to note that in contrast to the skin, which is enriched in leukocytes during acute stress, the peripheral blood and spleen are relatively depleted of leukocytes during acute stress. This stress-induced decrease in blood and spleen leukocyte numbers may contribute to the acute stress-induced suppression of immune function in these compartments.

Moreover, in contrast to acute stress, chronic stress has been shown to suppress skin CMI and a chronic stress-induced suppression of blood leukocyte redistribution is thought to be one of the factors mediating the immunosuppressive effect of chronic stress. Again, in what might appear to be contradicting results, chronic stress has been shown to enhance mitogen-induced proliferation of splenocytes and splenic IgM production. However, the spleen is relatively enriched with T cells during chronic glucocorticoid administration, suggesting that it may also be relatively enriched with T cells during chronic stress, and this increase in spleen leukocyte numbers may contribute to the chronic stress-induced enhancement of immune parameters measured in the spleen.

It is also important to bear in mind that the heterogeneity of the stress-induced changes in leukocyte distribution suggests that using equal numbers of leukocytes in a functional assay may not account for stress-induced changes in relative percentages of different leukocyte subpopulations in the cell suspension

being assayed. For example, samples that have been equalized for absolute numbers of total blood leukocytes from control versus stressed animals may still contain different numbers of specific leukocyte subpopulations (e.g., T cells, B cells, or NK cells). Such changes in leukocyte composition may mediate the effects of stress even in functional assays using equalized numbers of leukocytes from different treatment groups. This possibility needs to be taken into account before concluding that a given treatment changes an immune parameter on a per-cell rather than a per-population basis.

Conclusion

An important function of endocrine mediators released under conditions of acute stress may be to ensure that appropriate leukocytes are present in the right place and at the right time to respond to an immune challenge that might be initiated by the stress-inducing agent (e.g., attack by a predator or invasion by a pathogen). The modulation of immune cell distribution by acute stress may be an adaptive response designed to enhance immune surveillance and increase the capacity of the immune system to respond to challenge in immune compartments (such as the skin, the epithelia of the lung, and the gastrointestinal and urinary-genital tracts) that serve as major defense barriers for the body. Thus, neurotransmitters and hormones released during stress may increase immune surveillance and help enhance immune preparedness for potential (or ongoing) immune challenge.

Conclusion

Glossary

- Antigen** A foreign substance that induces an immune response.
- Cytokines** Protein hormones that mediate various functions of immune cells.
- Immune response** A reaction mounted by various components of the immune system, which consists of leukocytes, antibodies, cytokines and chemokines (messenger molecules), prostaglandins (inflammatory mediators), and accessory cells.
- Leukocytes** Cells that constitute the immune system. These include T and B lymphocytes, natural killer (NK) cells, monocytes/macrophages, and granulocytes.

Stress

Although the word stress generally has negative connotations, stress is a familiar aspect of life, being a stimulant for some but a burden for others. Numerous definitions have been proposed for the word stress. Each definition focuses on aspects of an internal or external challenge, disturbance, or stimulus; on the perception of a stimulus by an organism; or on a physiological response of the organism to the stimulus. Physical stressors have been defined as external challenges to homeostasis, and psychological stressors have been defined as the “anticipation justified or not, that a challenge to homeostasis looms.” (Sapolsky, 2005, p. 648). An integrated definition states that stress is a constellation of events, consisting of a stimulus (stressor) that precipitates a reaction in the brain (stress perception), which activates physiological fight-or-flight systems in the body (stress response). The physiological stress response results in the release of neurotransmitters and hormones that serve as the brain’s messengers to the rest of the body. This article examines the role played by stress and stress hormones in enhancing different aspects of the immune response. It is often overlooked that a stress response has salubrious adaptive effects in the short run, although stress can be harmful when it lasts a long time. An important distinguishing characteristic of stress is its duration and intensity. Thus, we define acute stress as stress that lasts for a period of a few minutes to a few hours and chronic stress as stress that persists for several hours per day for weeks or months. The intensity of stress may be gauged by the peak levels of stress hormones, neurotransmitters, by other physiological changes such as increases in heart rate and blood pressure, and by the amount of time for which these changes persist during stress and following the cessation of stress.

The Immune System

Immune Cells and Organs

The immune system consists of organs (bone marrow, spleen, thymus, and lymph nodes), cells (T cells; B cells; and natural killer, NK, cells; monocytes/macrophages; and granulocytes), and messenger molecules (cytokines, chemokines, and prostaglandins). These components of the immune system are spread throughout the body and are in constant communication with one another. The appropriate distribution of immune cells in the body is crucial to the performance of the different functions of the immune system.

Functions of the Immune System

The functions of the immune system may be classified into six major categories:

1. Constant surveillance of the body in preparation for potential immunological challenges (such as those described in the other five categories).
2. Detection and elimination of infectious agents such as bacteria, viruses, fungi, and other microorganisms and parasites from the body.
3. Detection and elimination of noninfectious foreign matter from the body.
4. Wound repair and healing.
5. Clearance of debris that may result from non-injurious events such as programmed cell death (apoptosis) in host tissues.
6. Detection and elimination of tumors and neoplastic tissue.

Thus, it has been suggested the immune system may be regarded as the body’s army with soldiers (immune cells) moving from their barracks (bone marrow, lymph nodes, spleen, thymus) through highways (blood vessels and lymphatic ducts) and patrolling almost all organs within the body, especially those organs (the skin, lining of gastrointestinal and urinary-genital tracts, lung, liver, lymph nodes, and spleen) that may serve as potential battle stations should the body’s defenses be breached. While performing their various functions, immune cells communicate with one another and with the rest of the body through messenger molecules such as the cytokines and chemokines.

Types of Immune Responses

Natural or innate immunity Natural or innate immune responses are initially mounted when an organism encounters an antigen or pathogen. These responses are rapidly activated and generally regarded as the first line of defense. Epithelial barriers, immune cells, the complement system, circulating proteins such as C-reactive protein, cytokines such as the α and β interferons (IFNs), tumor necrosis factor (TNF), interleukin (IL)-12, and IL-15 are involved in mediating innate immune reactions. Macrophages, neutrophils, and NK cells are the primary cellular mediators. Cells of the innate immune system recognize pathogens through surface receptors such as the toll-like receptors (TLRs), which recognize pathogen-associated molecular patterns (PAMPs). Innate immune responses are not enhanced by repeated exposure to antigens.

Acquired or specific immunity Acquired or specific immune responses are mounted following prior

exposure to an antigen; they are mediated by lymphocytes (T and B cells) and antibodies and are primarily regulated by lymphocyte-derived cytokines such as IL-2, IL-4, and IFN- γ . Acquired immune responses are directed against specific antigens and are often enhanced following repeated exposure to antigens. Acquired immunity can be divided into two broad categories: cell-mediated immunity (CMI) and humoral immunity.

Cell-mediated immunity CMI can be adoptively transferred from an immunized organism to naïve organism by the transfer of T cells and primarily involves cell-mediated clearing mechanisms. Intracellular infectious agents such as certain bacteria (e.g., *Listeria monocytogenes* or *Mycobacterium tuberculosis*) and viruses require a CMI response for their elimination. This response involves T helper (Th) cells which recognize infected cells with the help of specialized antigen-presenting cells (APC). On antigen recognition, Th cells release cytokines and chemokines, and they orchestrate a series of reactions involving cytolytic T cells (CTL), macrophages, and NK cells. These cells move to the site of infection and lyse or phagocytose infected cells and destroy them. In addition to their protective effects, CMI responses are also involved in harmful reactions such as organ transplant rejection, graft versus host disease, and certain autoimmune diseases. Delayed type hypersensitivity (DTH) is a form of CMI in which the macrophage is the major effector cell. The tuberculin skin test is a classic example of a CMI response. A characteristic CMI response peaks at 24–48 h following exposure to the antigen. Depending on the nature of the antigen, CMI reactions mediate beneficial (resistance to viruses, bacteria, and fungi) or harmful (allergic dermatitis, autoimmunity) aspects of the immune function.

Humoral immunity A humoral immune response is adoptively transferred from an immunized organism to a naïve organism by the transfer of cell-free plasma or serum and primarily involves antibody-mediated clearing mechanisms. Extracellular infectious agents such as bacteria (e.g., *Staphylococcus*, *Streptococcus*, or *Escherichia coli*), protozoan, and helminthic parasites require antibody-mediated responses for their elimination. Antibodies are proteins produced by B cells that neutralize extracellular infectious agents, which are then destroyed by macrophages, neutrophils, or complement proteins.

The integrated immune response It is important to note that, although immune reactions are classified

into different categories, an immune response is often a combination of innate as well as acquired immune reactions. *In vivo* immune responses necessarily involve intricate interactions between both the innate and adaptive arms of the immune system. Different components of the immune system work in synchrony to protect the body from infections, wounds, and tumors. Although mechanisms of self- and counter-regulation exist between various immune components, mechanisms also exist by which immune responses may be modulated or influenced by mediators such as hormones and neurotransmitters. Stress, and its consequent release of hormones and neurotransmitters, has been shown to influence specific immune parameters such as blood leukocyte numbers, NK cell activity, lymphocyte proliferation, antibody production, effector cell function, and CMI reactions. The immunoenhancing effects of stress are the focus of the rest of this article.

General Assumption: Stress Suppresses Immune Function and is Detrimental to Health – Reasons for Modifying This General Assumption

It is generally assumed that stress suppresses immune function and hence is detrimental to health. However, the suppression of immune function under all stress conditions should not be evolutionarily adaptive. It seems paradoxical that organisms should have evolved to suppress immune function at a time when an active immune response may be critical for survival, for example, under conditions of stress when an organism may be injured or infected by the actions of the stress-inducing agent (e.g., a predator). Stress is an intrinsic part of life for most organisms, and dealing successfully with stressors is what enables survival. Environmental challenges and most selection pressures, the chisels of evolution, are stressors that may be psychological (fear and anxiety), physical (wounding and infection), or physiological (food or water deprivation). One of the primary functions of the brain is to perceive stress and to warn and enable an organism to deal with its consequences. For example, when a gazelle sees a charging lion, the gazelle's brain detects a threat and orchestrates a physiological response that first prepares and then enables the gazelle to flee.

It has been suggested that under short-duration stress conditions, just as the stress response prepares the nervous, cardiovascular, musculoskeletal, and neuroendocrine systems for fight or flight, it may also prepare the immune system for challenges (e.g., wounding or infection) that may be imposed by the

stressor. In contrast to this hypothesis, it had previously been suggested that a stress-induced suppression of immune function may be evolutionarily adaptive because immunosuppression may conserve energy that is required to deal with the immediate demands imposed by the stressor. However, immunosuppression does not necessarily conserve energy, and some of the proposed mechanisms for immunosuppression, such as apoptosis of leukocytes, may expend rather than conserve energy. Moreover, the immune system may often be critically needed to respond immediately to the actions of the stress-inducing agent (e.g., wounding by a predator). Thus, whereas ovulation, copulation, and digestion can wait for the cessation of stress, the immune response cannot be assumed to be dispensable in terms of meeting the immediate demands of stress. Moreover, the time course for many of the proposed mechanisms for stress-induced immunosuppression, such as inhibition of prostaglandin synthesis, cytokine production, or leukocyte proliferation, is significantly longer than that seen during acute stress conditions. Thus, although energy conservation may play a role in stress-induced immunosuppression under some conditions, it is not clear that it does so under all stress conditions.

Another well-known paradoxical observation is that, on the one hand, stress is thought to suppress immunity and increase susceptibility to infections and cancer and, on the other, it is thought to exacerbate inflammatory (e.g., cardiovascular disease and gingivitis) and autoimmune (e.g., psoriasis, arthritis, and multiple sclerosis) diseases that should be ameliorated by the suppression of immune function. If stress were solely immunosuppressive, we would expect stress to ameliorate, not exacerbate, these diseases. A stress-induced enhancement of immune function would help explain the stress-induced exacerbation of diseases mediated by immunopathological reactions.

Keeping these considerations in mind, and based on their initial observations of the effects of stress and of the circadian corticosterone rhythm on leukocyte redistribution in the body, Dhabhar and McEwen demonstrated that stress has bidirectional effects on immune function such that acute stress is immunoenhancing and chronic stress is immunosuppressive. This article focuses on the immunoenhancing aspects of stress.

Studies Showing Stress-Induced Enhancement of Immune Function

A majority of studies in the field of psychoneuro-immunology have focused on the immunosuppressive

effects of stress, but several studies have also revealed that stress can be immunoenhancing. A stress-induced enhancement of immune function may be an important evolutionarily adaptive response that prepares an organism for potential immunological challenges for which stress perception by the brain, and subsequent stress hormone and neurotransmitter release, may serve as an early warning. Studies showing stress-induced enhancements in immune parameters *in vivo* and *in vitro* are briefly reviewed next.

Skin Cell-Mediated Immunity

There exist several mechanisms by which stress may enhance immune function. Studies showed that acute stress (2-h restraint) results in a significant redistribution of leukocytes from the blood to other organs (the skin, lymph nodes, and bone marrow) in the body and that adrenal stress hormones are the major mediators of this leukocyte redistribution. Because the skin was one of the targets to which leukocytes trafficked during stress, it was hypothesized that such a leukocyte redistribution may increase immune surveillance and consequently enhance immune function should the skin be exposed to an antigen following acute stress.

To test this hypothesis, researchers examined the effects of acute stress on skin immunity, using rodent models of CMI. In order to induce CMI, researcher initially sensitized animals to 2,4-dinitro-1-fluorobenzene (DNFB) by administering the chemical antigen to the skin of the dorsum. The sensitization phase of a CMI reaction is one in which the organism develops an immunological memory (through the generation of memory T cells) for the antigen with which it is immunized. Following sensitization, the ability of the animals to mount a CMI response against DNFB was examined by administering DNFB to the dorsal aspect of the right pinna. The CMI response was subsequently measured as an increase in pinna thickness that was proportional to the intensity of the ongoing immune reaction. This phase, also known as the challenge phase, involves the recruitment of memory T cells and effector cells such as macrophages, which mount an immune response against the antigen to which the animal was previously sensitized. Acute restraint stress administered immediately before the introduction of the antigen resulted in a large and long-lasting enhancement of skin CMI. Histological analysis identified significantly larger numbers of leukocytes in the skin of stressed animals both before and after exposure to antigen, and this suggested that a stress-induced redistribution of leukocytes was one of the factors mediating the stress-induced enhancement of skin

immunity. Acute stress has similarly been shown to enhance skin CMI in mice and, under certain conditions, may also enhance the CMI response in human subjects.

It has also been shown that the acute stress-induced enhancement of skin CMI is mediated by adrenal hormones. Thus, adrenalectomy, which eliminates the glucocorticoid and epinephrine stress response, eliminated the stress-induced enhancement of skin CMI. Low-dose corticosterone or epinephrine administration significantly enhanced skin CMI and produced a significant increase in T-cell numbers in the lymph nodes draining the site of the CMI reaction. These results suggest a novel role for adrenal stress hormones as endogenous immunoenhancing agents. They also show that hormones released during an acute stress response may help prepare the immune system for potential challenges (e.g., wounding or infection) for which stress perception by the brain may serve as an early warning signal.

Humoral Immunity

Wood et al. showed that exposure to foot shock stress enhanced humoral as well as CMI to keyhole limpet hemocyanin (KLH). These investigators administered a single acute foot shock session on days -1, 0, 1, and 3, relative to sensitization (day 0). They observed that, compared to nonstressed controls, animals stressed on days 0 or 1 showed enhanced immune responses with respect to serum anti-KLH IgG levels, splenocyte proliferation, and skin CMI to the KLH antigen. Similar results were almost simultaneously reported by researchers who found that the timing of stressor exposure was critical for determining its immunoenhancing effects. Several other studies have reported stress-induced enhancement of humoral immune responses. For example, stress has been shown to accelerate antigen removal in mice, rats, and pigs. It has also been proposed that glucocorticoids may shift the balance of an ongoing immune response in favor of humoral immunity, and physiological doses of glucocorticoids have been shown to enhance immunoglobulin production by mitogen- and IL-4-stimulated human lymphocytes in culture.

Cytokine Function

Several lines of evidence indicate that glucocorticoid stress hormones may act synergistically with cytokines to enhance specific immune reactions. Thus, although glucocorticoids inhibit the synthesis of cytokines under some conditions, they have also been shown to induce the release and potentiate the actions of cytokines under other conditions. For example, stress has been shown to induce increases in plasma

levels of IL-1, IL-6, and glucocorticoids to induce the production of migration inhibitory factor (MIF), which is, in turn, proposed to counter the actions of glucocorticoids. Moreover, glucocorticoids synergistically enhance the induction of acute phase proteins by IL-1 and IL-6. Glucocorticoids similarly enhance the biological responses of other cytokines such as IL-2, IFN- γ , granulocyte colony-stimulating factor (G-CSF), granulocyte macrophage colony-stimulating factor (GM-CSF), and oncostatin M. It has been suggested that synergistic interactions between glucocorticoids and cytokines may be mediated by the glucocorticoid-induced upregulation of cytokine receptors on target cells.

Proliferative Responses and Phagocytosis

Acute stressors such as handling and foot shock have been shown to enhance the mitogen-induced proliferation of blood lymphocytes. Acute stress has also been shown to enhance macrophage phagocytic function and blood NK cell activity. Several studies have shown that the *in vitro* administration of stress hormones to immune cells can enhance different aspects of the immune function. Low physiological concentrations of corticosterone have been shown to stimulate mitogen- and anti-T-cell receptor-induced proliferation of splenocytes. Similarly, glucocorticoid hormones have been shown to enhance nitric oxide and IL-1 β secretion by macrophages.

Functional Implications

The studies described here show that, under certain conditions, stress can enhance immune responses. These studies may help reconcile the apparent contradiction between reports showing that, on the one hand, stress suppresses immunity and increases susceptibility to infections and cancer but, on the other, exacerbates autoimmune diseases that should be ameliorated by the suppression of immune function. For example, under natural conditions, acute stress may serve a protective role by enhancing an immune response directed toward a wound or infection. However, a stress-induced enhancement of immune function could also be detrimental if the immune response is directed against an innocuous (poison ivy, nickel in jewelry, latex, etc.) or autoimmunogenic antigen, and this could explain the well-known stress-induced exacerbations of autoimmune diseases. It is also known that chronic stress suppresses immune function. This may explain stress-induced exacerbations of infections and cancer and the stress-induced suppression of wound healing. It has also been reported that high doses or prolonged administration of corticosterone or low doses

of dexamethasone are potently immunosuppressive, in keeping with their clinically well-known antisuppressive effects.

It is important to note that humans as well as animals experience acute or chronic stress as an intrinsic part of life. They also experience stress in conjunction with many standard diagnostic, clinical, and experimental manipulations. Unintended stress may significantly affect diagnostic measures and overall health outcomes. Thus, it may be important to account for the effects of acute versus chronic stress when conducting clinical, diagnostic, or experimental manipulations.

The Stress Spectrum Hypothesis

In view of the data presented here, and in view of the widely demonstrated immunosuppressive effects of stress, Dhabhar and McEwen proposed that a stress response and its consequent effects on immune function may be viewed in the context of a stress spectrum. One region of this spectrum is characterized by acute stress or eustress (i.e., conditions of short-duration stress that may result in immunopreparatory or immunoenhancing physiological conditions). An important characteristic of acute stress is a rapid physiological stress response mounted in the presence of the stressor, followed by a rapid shut-down of the response on cessation of the stressor. The other region of the stress spectrum is characterized by chronic stress or distress (i.e., repeated or prolonged stress that may result in dysregulation or suppression of immune function). An important characteristic of chronic stress is that the physiological response either persists long after the stressor has ceased or is activated repeatedly, which results in an overall integrated increase in the exposure of the organism to stress hormones. The concept of allostatic load has been proposed to define the psychophysiological wear and tear that takes place while different biological systems work to stay within a range of equilibrium (allostasis) in response to the demands placed by internal or external chronic stressors. We suggest that conditions of high allostatic load result in the dysregulation or suppression of immune function. Significantly, a disruption of the circadian corticosterone/cortisol rhythm may be an indicator and/or mediator of distress or high allostatic load.

The stress spectrum also proposes that acute or chronic stress is generally superimposed on a psychophysiological health maintenance equilibrium. The extent and efficiency with which an organism returns to its health maintenance equilibrium after stress depends on resilience, which we define as the reserve capacity of psychophysiological systems to recover

from challenging conditions. Factors such as coping mechanisms, sense of control, optimism, social support, early life experiences, learning, genetics, and sleep may be important mediators of psychological resilience. Factors such as neuroendocrine reactivity, genetics, environment, nutrition, and sleep may be important mediators of physiological resilience. The psychophysiological basis of resilience and reserve capacity are underinvestigated and provide an important opportunity for future research.

The stress spectrum, taken together with the preceding discussion, shows that the duration, intensity/concentration, and timing of exposure to stressor-induced physiological activation (neurotransmitters, hormones, and their molecular, cellular, organ-level, and systemic effects) are critical for determining whether stress enhances or suppresses/dysregulates immune function. The model shows that the stressor itself can be acute or chronic. Stress perception and processing by the brain and mechanisms mediating psychological and physiological resilience are critical for determining the duration and magnitude of the physiological stress response. Psychological resilience mechanisms are especially important in humans because they can limit the duration and magnitude of chronic stress responses. Psychogenic stressors are also very important in human subjects because they can generate stress responses long after stressor exposure (e.g., posttraumatic stress disorder following a severe traumatic experience or, in a milder form, lingering anger/mood disturbance following a social altercation) or even in the absence of a physical stressor or salient threat (e.g., worrying about whether one's romantic feelings will be reciprocated). Therefore, following stressor exposure and its processing by the brain, there ensues a physiological stress response. This response may consist of acute or chronic physiological activation (neurotransmitters; hormones; and their molecular, cellular, organ-level and systemic effects) that results in psychophysiological states that have different effects on overall health and immune function.

Conclusion

Stress has long been suspected to play a role in the etiology of many diseases, and numerous studies have shown that stress can be immunosuppressive and hence may be detrimental to health. Moreover, glucocorticoid stress hormones are widely regarded as being immunosuppressive and are used clinically as anti-inflammatory agents. Due to a host of psychosociopolitical factors, stress has unfortunately become an increasing and inevitable part of people's lives. Stress is also a major factor during the

diagnosis, treatment, and follow-up of most diseases. However, as this discussion shows, some stress conditions (i.e., acute or short-duration stressors) produce immunoenhancement. A determination of the physiological mechanisms through which stress and stress hormones enhance or suppress immune responses may help our understanding and treatment of diseases thought to be affected by stress. Thus, future studies should aim at developing biomedical treatments that harness an individual's physiology to selectively enhance (during vaccination, wounding, infections, or cancer) or suppress (during autoimmune or inflammatory disorders) the immune response, depending on what is most beneficial for the patient.

Glossary

<i>Adaptive (acquired) immune response</i>	Immunity mediated by lymphocytes and characterized by antigen-specificity and memory.
<i>Complement</i>	A group of serum proteins, some of which act in an enzymatic cascade, producing effector molecules involved in inflammation (C3a, C5a), phagocytosis (C3b), and cell lysis (C5b–C9).
<i>Cytokines</i>	Low-molecular-weight proteins that stimulate or inhibit the differentiation, proliferation, or function of immune cells.
<i>Dendritic cell</i>	Refers to an interdigitating dendritic cell which is major histocompatibility complex (MHC) class II-positive, Fc receptor-negative, and presents processed antigens to T cells in the T cell areas of secondary lymphoid tissues.
<i>Granulocyte</i>	Myeloid cells containing cytoplasmic granules (i.e., neutrophils, eosinophils, and basophils).
<i>Innate immune response</i>	Immunity which is not intrinsically affected by prior contact with antigen, i.e., all aspects of immunity not directly mediated by lymphocytes.
<i>Primary immune response</i>	The relatively weak immune response which occurs upon the first encounter of naive lymphocytes with their specific antigen.
<i>Secondary immune response</i>	The much stronger immune response which occurs upon the second encounter of primed lymphocytes with their specific antigen.
<i>Toll-like receptors (TLRs)</i>	A family of pattern recognition receptors involved in the detection of structures associated with pathogens or damaged host tissues.

The immune system has evolved to protect the body from foreign pathogens. It does so using quite a number of different cell types, most of which arise from pluripotent hematopoietic stem cells in the bone marrow and are collectively referred to as leukocytes (white blood cells). These stem cells can enter one of two differentiation pathways, the myeloid pathway which gives rise to monocytes/macrophages, dendritic cells, granulocytes (neutrophils, eosinophils, basophils, and mast cells), erythrocytes, and platelets, and the lymphoid pathway which gives rise to lymphocytes and natural killer (NK) cells ([Figure 1](#)). The bone marrow is referred to as a primary lymphoid organ and is where many of these cell types, including the B lymphocytes (B cells), reach maturity. However, the precursors of the T lymphocytes (T cells) need to leave the bone marrow and travel to the thymus in order to become fully developed. Given that a thymus is obligatory for the generation of T cells it is also referred to as a primary lymphoid organ. Upon maturation the lymphocytes, together with specialized antigen-presenting dendritic cells, primarily locate to secondary lymphoid organs (mucosa-associated lymphoid tissue (MALT), lymph nodes, and spleen) where the local architecture permits optimal stimulation of the immune response.

In order to become activated, the cells of the immune system need to detect the presence of a pathogen. Structures that can potentially be recognized by the immune system are broadly referred to as antigens and comprise an almost unlimited variety of protein, carbohydrate, lipid, and small molecular moieties. Antigenic structures are therefore associated not only with foreign organisms (viruses, bacteria, fungi, and parasites) and molecules (ingested, inhaled, or absorbed substances) but also the body's own (self) molecules and cells. Despite this capacity of the immune system to recognize an almost infinite variety of antigens, it must avoid making potentially damaging responses against self-antigens and against beneficial commensal organisms, food antigens, and so on. Thus, the cells of the immune system normally respond when they detect structures associated with pathogenic organisms.

Innate and Adaptive Immune Responses

Most cells of the immune system react with similar vigor however many times they encounter the same pathogen. This type of response is referred to as innate immunity ([Figure 2](#)) and involves phagocytic cells and

Figure 1 The major players in the immune response derived from hematopoietic stem cells in the bone marrow. Myeloid and lymphoid progenitors differentiate into a number of different cell types that, upon activation, mediate various immunological functions (examples of which are indicated). ¹Monocytes in the blood have functions that generally become more pronounced when these cells enter the tissues and differentiate into macrophages. ²APC, professional antigen-presenting cell that uses MHC class II molecules to present processed antigen to CD4 (usually helper) T cells. ³Dendritic cells (DC) come in a variety of forms. In addition to the myeloid dendritic cells, lymphoid dendritic cells (not shown) arise from lymphoid progenitors and have similar immunological functions to those of myeloid DC. Note that DCs are the only cell type that can act as APCs for naive T cells (i.e., T cells that have not previously encountered an antigen). There is also an entirely separate population of cells with a dendritic morphology that are present in secondary lymphoid organs and are referred to as follicular dendritic cells (FDC). FDC are nonphagocytic and lack the MHC class II required of professional APC, but instead present nonprocessed antigen (held on their surface in the form of immune complexes) directly to B cells. ⁴Blood basophils and tissue mast cells share functional properties but it is thought that they are independently derived rather than blood basophils giving rise to tissue mast cells. ⁵Immune complexes are composed of antigen bound to antibody and also often including complement components. ⁶Th cells assist other cells in the immune system partly by secreting immunostimulatory cytokines but also using cell-contact dependent mechanisms. ⁷Treg cells are heterogeneous, some inhibit other cells in the immune system by secreting cytokines with immunosuppressive properties while others use cell-contact dependent mechanisms to suppress immune responses. ⁸B cells can act as professional APCs for antigen-experienced Th cells, and when activated can themselves secrete cytokines. When B cells differentiate into plasma cells their role is to secrete large amounts of antibody.

Figure 2 Some innate and adaptive immune responses. Humoral responses are those that are mediated by soluble molecules such as complement and cytokines in the innate response and antibody in the adaptive response. MHC class II⁺ dendritic cells act as professional APC to present processed antigen to T cells, while the entirely different follicular dendritic cells (FDC) can present native antigen to B cells. Ag, antigen; IFN γ , gamma interferon; M ϕ , macrophage. Green wavy lines indicate processes that activate, whereas red dotted lines indicate processes that inhibit or kill. (Modified with permission from Delves PJ, Martin SJ, Burton, DR, and Roitt IM. (2006). *Roitt's essential immunology*, 11th edn. Oxford: Blackwell Publishers).

NK cells, as well as basophils and mast cells. The phagocytic cells comprise short-lived neutrophils present in both the circulation and in the tissues, blood monocytes which differentiate into the more actively phagocytic macrophage upon entering the tissues, and dendritic cells in the tissues. Eosinophils are also weakly phagocytic but they are more adept at killing organisms that are too large to be engulfed and onto which they release toxic molecules. Basophils in the blood, and the functionally related mast cell in the tissues, release inflammatory mediators such as histamine, prostaglandins, and leukotrienes. The NK cells, present in both the circulation and the tissues, kill infected or malignant cells. Thus, the innate immune response can call upon a number of fundamentally different cell types. In contrast, the adaptive (also referred to as acquired) immune response is mediated by lymphocytes. These cells are exquisitely specific for individual antigens and when they encounter 'their' antigen for the first time they mount a primary immune response that produces not only cells and molecules to deal with the threat at hand but also memory cells. The latter constitute a population of lymphocytes that are expanded in number and have the capacity to generate the qualitatively and quantitatively superior secondary immune response. Of the two main populations of lymphocytes, B lymphocytes (B cells) and T lymphocytes (T cells), it is the B cells that are responsible for producing antibody molecules. T cells can be divided into three main subpopulations. Helper T cells (Th) assist, and regulatory T cells (Treg) can suppress, other cells in the immune response. Cytotoxic T cells (Tc), also referred to as cytotoxic T lymphocytes (CTL), kill infected or foreign eukaryotic cells. Most Th and Treg express a molecule called CD4 on their cell surface, whereas most Tc express CD8 instead.

Recognition of Pathogens and Other Antigens

In order to mount an immune response the cells of the immune system need to detect the presence of a threat. They do this using cell surface receptors which can be grouped into two main types: broadly reactive receptors and antigen-specific receptors.

Broadly Reactive Receptors

The cells involved in innate immune responses have a large number of receptors which are each encoded by entirely separate genes and which recognize structures that are common to many different organisms. These types of receptors are referred to as pattern recognition receptors (PRR) and their ligands

designated pathogen-associated molecular patterns (PAMPs). Recently PRRs have been found to also be present on the cells of the adaptive immune response (i.e., lymphocytes), and some PRRs have been shown to recognize certain endogenous (self) ligands as well as recognizing PAMPs. Although the receptors are highly specific for the structures they recognize, their ligands are molecules that are widely distributed amongst many different species of pathogen. Examples include the toll-like receptors (TLRs; such as TLR3 which recognizes viral double-stranded ribonucleic acid (RNA) and TLR5 which detects bacterial flagellin) and the mannose receptor. The latter binds to the terminal mannose structure characteristic of prokaryotes but which is always covered by other sugars in glycoproteins of eukaryotic origin.

Antigen-Specific Receptors

Lymphocytes possess highly antigen-specific receptors on their cell surface. The B-cell receptor for antigen is a transmembrane version of the antibody molecule, while the analogous receptor on T lymphocytes consists of an $\alpha\beta$ or $\gamma\delta$ T-cell receptor (TCR) heterodimer. These receptors contain variable regions which, as their name suggests, vary from one receptor to another and which confer antigen specificity. All the antigen receptors on an individual lymphocyte will possess the same variable region sequence, but those on a different lymphocyte will bear a different variable region and hence specificity for a different antigen. The receptors are generated by a unique gene recombination mechanism in which the nucleotide sequence encoding the variable region of the protein is constructed from more than one gene. Thus, one gene sequence is picked in a fairly random fashion from each of two (for immunoglobulin (Ig) light chains and for TCR α or γ chains) or three (for Ig heavy chains and for TCR β or δ chains) gene pools referred to as variable (V), diversity (D, if utilizing all three gene pools), and joining (J) gene segments and these sequences spliced next to each other ([Figure 3](#)). The Ig genes undergo recombination in the precursors of B lymphocytes while TCR genes undergo recombination in early T cells. In each lymphocyte a different recombination occurs and, together with a variety of additional molecular mechanisms which further increase diversity, leads to an almost infinite variety of antigen-specific receptors being generated. Therefore one lymphocyte will have antigen receptors that are specific for a particular component of streptococcus, another lymphocyte will be specific for an antigen from staphylococcus, another for a part of the influenza virus, and so on. There will only be a handful of lymphocytes specific for each antigen but collectively

Figure 3 Antigen receptor gene recombination. In this example, immunoglobulin heavy chain (IgH) gene recombination is illustrated, but immunoglobulin light chain genes and the TCR genes undergo similar recombination processes in order to create a large number of different variable region sequences from a relatively small gene pool. Here the B cell has recombined the V3, D2, and J4 immunoglobulin heavy chain gene segments (not drawn to scale) and is utilizing the C_μ constant region gene segment from a primary RNA transcript that also includes C_δ . Alternative splicing of the primary RNA transcript is used to also produce IgD with the same antigen specificity. A different B cell might recombine V42, D16, and J6, etc., and would therefore have a different heavy chain variable region sequence. Recombination to provide variability for the immunoglobulin light chain variable region (not shown) is brought about by similar mechanisms using separate gene loci containing only V, J, and C segments. The heavy chain constant region gene transcription can include transmembrane exons. The heavy and light chain proteins polymerize into the 4 chain ($2H + 2L$) immunoglobulin molecule, which then sits in the cell surface membrane to function as the antigen-specific B-cell receptor. In plasma cells the transmembrane exons are not utilized and a secreted version of the antibody, with identical antigen-specificity, is produced. In the case of IgM the antibody polymerizes into pentamers prior to secretion. Class switching occurs later in the immune response with C_μ and C_δ usage being replaced with, for example, $C_\gamma1$ which specifies the IgG1 subclass of antibody but utilizing the same variable region and thus with the same antigen specificity. The areas of the variable region in both the heavy and the light chain which make contact with the antigen are referred to as complementarity determining regions (CDR).

all the lymphocytes will provide cover against virtually all antigens that might be encountered.

Generation of the Immune Response

Innate responses are initiated when the PRRs on the surface of phagocytic and other cells detect the presence of PAMPs. Additionally, foreign antigens will very often become coated with proteins that are generated by the complement system, a cascade of molecules activated during immune responses. Later on in the immune response the antigen will additionally be coated with antibody. Among the many different types of molecules on the surface membrane of immune system cells are receptors for complement molecules and for the nonantigen-binding end (Fc) of the antibody molecule. Microorganisms coated with antibody and/or complement are said to be opsonized for phagocytosis, the antibody and complement linking the organism to the phagocyte. Complement carries out other functions; it acts

as a chemotactic factor for phagocytes, it stimulates the release of inflammatory mediators from mast cells, and can mediate lysis of certain strains of bacteria.

The response of lymphocytes to an encounter with an antigen is somewhat different to that of the cells of the innate immune response. Whereas the latter go straight ahead with the task required, be it phagocytosis or the release of inflammatory mediators, the lymphocyte undergoes rapid cell division. The clone of lymphocytes with the appropriate antigen-specific receptor thus become greatly amplified in number during the adaptive immune response. T cells (at least the main population of T cells which bear an $\alpha\beta$ TCR) cannot recognize antigens directly, but instead see antigen that has been processed and presented. With respect to Th cells which have not previously encountered their specific antigen, i.e., naive T cells, this involves dendritic cells which phagocytose or endocytose antigen, then demolish its protein components using proteases which generate short peptides

of around 15 amino acids in length within the endosomal compartment of the cell. While still inside the endosomes these antigenic peptide fragments are combined with major histocompatibility complex (MHC) molecules of the class II type, and the complex of antigen peptide plus MHC class II is transported to the cell surface of the dendritic cell. It is the combination of peptide–MHC that is recognized by the TCR on the T cell, with the dendritic cell also expressing other cell-surface molecules such as CD80 and CD86 which supply the potent co-stimulation obligatory for the activation of naive T cells. Both macrophages and B cells also express peptide-bearing MHC class II molecules on their cell surface but due to their less profound ability to provide high levels of co-stimulation they only activate antigen-experienced T cells. Dendritic cells, macrophages, and B cells are collectively referred to as professional antigen-presenting cells (APC), a euphemism for cells which present antigen to CD4 T cells using MHC class II molecules. However, virtually all cells in the body are able to present peptide antigens using MHC class I molecules. In this case the peptides are usually generated from antigens present within the cytosol of a cell, including foreign antigens such as viruses. Cytosolic proteolysis for subsequent antigen presentation utilizes a modified version of the proteasome enzyme complex that carries out the normal cellular degradative processes. Peptide–MHC class I complexes expressed on the surface of infected cells are recognized by CD8+ Tc cells. Thus CD4+ T cells use their $\alpha\beta$ TCR to recognize peptides presented by MHC class II molecules on professional APC whereas CD8+ T cells use their $\alpha\beta$ TCR to recognize peptides presented by MHC class I molecules on infected cells.

The MHC is given a different name in different species, in humans it is referred to as human leukocyte antigen (HLA; although present not only on leukocytes) while in mice it is called H-2. In humans there are three main MHC class I gene loci, HLA-A, HLA-B, and HLA-C, and three class II loci, HLA-DP, HLA-DQ, and HLA-DR. In mice the main class I loci are H-2K and H-2D while the class II loci are referred to as I-A and I-E. The MHC molecules are encoded by the most polymorphic of all of the genes in the genome, and thus can vary enormously from individual to individual. It is this MHC polymorphism that is largely responsible for the immune system recognizing and subsequently rejecting organs or tissues from other members of the same species (allografts). The MHC genes are co-dominantly expressed and therefore each individual expresses two polymorphic variants of HLA-A, two of HLA-B, and so on. Certain variants are more common in the population than others and with common variants such as HLA-A2

in Caucasians it is quite frequently the case that an individual will be homozygous at that particular genetic locus.

The Anatomy of the Immune Response

The cells of the innate response such as phagocytic cells can act individually at the site of an infection. They are attracted to such sites by chemotactic factors, and their passage from the circulation out into the tissues is facilitated by the upregulated expression of adhesion molecules on vascular endothelial cells, ligands for which are expressed on the leukocyte cell surface.

As discussed previously, the Th cells of the adaptive response need to interact with professional APC in order to be activated. This requires cell–cell contact as the TCR on the T cell must bind to the peptide–MHC on the APC. The Th cells are also required to be in close proximity with the cells that will receive their help, which is provided by a combination of soluble molecules such as cytokines and by interactions between cell surface molecules on the Th cell and on the cell being helped. There are different subsets of cytokine-producing Th cells (e.g., Th1 cells, Th2 cells) and depending upon which subset is involved, the cytokine-mediated help that is given may facilitate antibody production by B cells, activation of Tc to kill infected cells, or enhancement of macrophage function ([Figure 2](#)). Given that Th, Tc, and B cells are all antigen-specific, that there are only a handful of cells specific for a given antigen, and that T cells require antigen to be presented to them, there is a need for a meeting place where the relevant cells can get together. This is the role of the secondary lymphoid organs; the spleen, lymph nodes, and MALT. These are the locations in which adaptive immune responses are initiated. Because the majority of pathogens will enter the body by ingestion or inhalation the MALT collectively provides a critical first line of defense against infection and acts as a major effector site for protective immune responses.

Protective Immune Response

The immune response is aimed at destroying foreign pathogens. Engulfment of microorganisms by phagocytes leads to their elimination when a wide variety of microbicidal compounds including toxic metabolites of oxygen such as hydroxyl radicals and enzymes such as lysozyme kill the invader. Eosinophils release toxins to achieve extracellular killing. Mast cells and basophils produce a plethora of molecules which collectively facilitate an acute inflammatory response with recruitment of leukocytes to the

site of the infection. Infected cells, and some tumor cells, are dealt with by Tc and NK cells which can both induce apoptotic cell death in the target cell. Many cells in the body are capable of releasing cytokines but Th cells are particularly adept at doing so. In addition to providing help for other cells in the immune system, some cytokines can be directly cytotoxic (e.g., tumor necrosis factor (TNF)). B cells produce antibody molecules which are collectively found in their secreted form at high levels ($10\text{--}15\text{ mg ml}^{-1}$) in the circulation and, with the exception of the physically large pentameric IgM, also readily diffuse into the tissues. Antibodies are able to directly neutralize bacterial toxins, prevent viruses binding to cells, agglutinate microorganisms and thereby immobilize them, activate complement, opsonize microorganisms for phagocytosis, and mediate antibody-dependent cellular cytotoxicity (ADCC) in which leukocytes of various types become linked by antibody to infected cells and then kill them.

Avoidance of Harmful Immune Responses

The immune system can potentially react against the body's own components, resulting in immunity to self (autoimmunity). This only becomes a problem if the autoimmune reactions cause pathology, in which case the individual develops an autoimmune disease. Approximately 3–5% of individuals develop autoimmune disease at some time in their life. There are an extremely large number of different diseases in which autoimmune responses are thought to play a role, with the most common including psoriasis, thyroid autoimmune diseases (primarily Hashimoto's thyroiditis and Graves' disease), rheumatoid arthritis, vitiligo, systemic lupus erythematosus, Sjögren's syndrome, celiac disease, Crohn's disease, pernicious anemia, ankylosing spondylitis, type I (insulin-dependent) diabetes, and multiple sclerosis. The fact that the vast majority of individuals do not develop pathogenic autoimmune responses is due to the phenomenon of immunological tolerance. Encounter with self-antigen early on in the development of a lymphocyte leads to its clonal deletion by apoptosis. This occurs in the thymus for T cells and in the bone marrow for B cells. The T cells undergo thymic education involving positive and negative selection events in the thymus. Cells are positively selected if the random rearrangement of their TCR genes generates a receptor capable of recognizing peptides presented by that individual's polymorphic variants of MHC (self-MHC). However, if the TCR recognizes peptides derived from self antigens then a subsequent negative selection step will induce apoptosis of the autoimmune T cell. Thus, the only T cells which leave

the thymus are ones that recognize foreign peptides presented by self-MHC. A somewhat similar process of negative selection occurs for B cells in the bone marrow, although their antigen receptor (the antibody molecule) recognizes antigen directly and therefore there is no requirement for positive selection for recognition of self-MHC molecules. The clonal deletion of T and B cells is not foolproof and some of the cells that leave the primary lymphoid organs are self-reactive. Therefore there are backup mechanisms to prevent harmful autoimmunity arising. Pathogenic foreign antigens are normally seen in the context of co-stimulatory activity whereas self-antigens do not provide co-stimulatory signals. When the lymphocyte receives a signal only through its antigen receptor in the absence of co-stimulation the result is not cell activation but rather cell inactivation, a process referred to as anergy. Unlike clonal deletion where the cell is eliminated, this leaves anergic cells which potentially can be re-activated. A further level of control rests with Treg cells that act to suppress any potentially harmful self-reactive cells. There are a number of different types of Treg cells, some of which arise naturally in the thymus and exert their effect via poorly understood cell contact-dependent mechanisms. Other Treg cells are induced to secrete cytokines that can mediate immunosuppressive activity, such as interleukin (IL)-10 and transforming-growth factor- β (TGF β).

While the avoidance of harmful immune responses to self-antigens is something that operates with a fair degree of success, the capacity of the body to prevent allergic responses to what should be innocuous foreign antigens would appear to be rather less effective. A substantial minority of individuals (estimates vary, but perhaps even as many as 45% of children and 30% of adults) suffer from allergies to varying degrees. This frequently involves atopy, a capacity to produce raised levels of the IgE class of antibody against the allergen. The class of antibody is of paramount importance here because the IgE becomes bound to the surface of mast cells and basophils by virtue of the fact that these cells possess high-affinity receptors for the Fc region of IgE (Fc ϵ R). If the IgE has specificity for environmental antigens (allergens) these cross-link the IgE molecules. As a consequence, cross-linking of the Fc ϵ Rs occurs leading to degranulation of the cells with the release of inflammatory mediators such as histamine.

Neuroendocrine-Immune Interactions

Although immune responses are driven by encounter with antigen and subject to regulation by a variety of cells and molecules which are clearly components of

the immune system, it is also known that factors such as nutrition, hormones, and neuropeptides can modify the immune response. Stressors such as exam anxiety, restraint, and noise are known to influence various immune functions including lymphocyte proliferation, IgA secretion, phagocytosis, and the activity of NK cells. Receptors for endorphins, enkephalins, acetylcholine, β -adrenoceptor agents, corticosteroids, insulin, growth hormone, estradiol, testosterone, and prolactin have all been described on various types of immune cell and their expression presumably infers some functional significance. To give an example, the cytokines IL-1, IL-6, and TNF act via the hypothalamic-pituitary-adrenal (HPA) axis to stimulate the release of glucocorticoids which are then capable of downregulating the activity of both Th1 cells and macrophages. Androgens and glucocorticoids generally suppress, while growth hormone, thyroxine, and insulin generally stimulate, immune responses. Lymphoid tissues, including the thymus, spleen, and lymph nodes, are richly innervated by norepinephrine-releasing sympathetic neurons. There is evidence from studies in knockout mice that in the absence of this neurotransmitter there is impaired production of the Th1-derived cytokines interferon (IFN) γ and TNF in response to challenge with antigen. Dendritic cells bear β -adrenoceptors and it has also been suggested that sympathetic nerves may be involved in controlling the migration of these APCs from the sites of inflammation to the local draining lymph nodes.

Allostasis

Type I and Type II Allostatic Responses

The Allostatic Modulation of Immune Suppression

T Cell Anergy and Apoptosis

A New Strategy: Molecular Cartography

Glossary

<i>Allostasis</i>	Psychobiological process that brings about stability through change of state consequential to stress. The allostatic response encompasses a range of psychobiological outcomes that reflect physiologically important changes in the balance between the psychoneuroendocrine and the immune systems. Allostasis overload leads to statistically significant and clinically relevant damage to the organism due to excessive energy expenditure in the response to stress.
<i>Anergy</i>	A state of immune unresponsiveness, induced as soon as the antigen receptor of the T cell is stimulated, which stops T cell responses waiting for second signal from the antigen-presenting cell.
<i>Apoptosis</i>	The process of programmed cell death needed to eliminate cells that represent a threat to the integrity of the organism.
<i>Circadian</i>	A term derived from the Latin <i>circa diem</i> meaning about a day, refers to biological rhythms that have a cycle of about 24 hours.
<i>Molecular cartography</i>	The science of recognizing and identifying multifaceted and intricate array of gene interaction and gene products that characterize the function of each individual cell in the context of cell–cell interaction, tissue, and organ function.

The renowned XIX century French physiologist, Claude Bernard (1813–78) first proposed that defense of the internal milieu (*le milieu intérieur*, 1856) is fundamental to physiological regulation, from when the phrase homeostasis originated. Walter Cannon (1871–1945) proposed that organisms engage in a

dynamic process of adjustment of the physiological balance of the internal milieu in response to changing environmental conditions. Hans Selye (1907–82) established the cardinal points of the generalized stress response in his demonstration of concerted physiological responses to stressful challenges.

The immune response is finely regulated at the molecular, cellular, and physiological levels. Bacteriokines (i.e., bacterial cytokine inducers), produced by infectious pathogens, contribute to the control of the pathological inflammatory response. This article focuses on the homeostasis of the immune response from the perspective of the psychoneuroendocrine and cellular events that contribute to the suppression of immunity in response to stressors.

Allostasis

Allostasis refers to the psychobiological process that brings about stability through change of state consequential to stress. Psychoemotional stress can be defined as a perceived lack of fit of one's perceived abilities and the demands of the environment (i.e., person/environment fit). The perception of stress leads to anxiety, irritability and anger, tension, depressed moods, fatigue, a compendium of symptoms referred to as the sickness behavior (e.g., lethargy, nausea, and fever), and to a set of other bodily manifestations, including perspiration, blushing or blanching of the face, increased heart rate or decreased blood pressure, and intestinal cramps and discomfort, and suppressed immune resistance to antigenic challenges.

Sterling and Eyer (1988) defined allostasis as the set of mind–body systemic events aimed at regulating the recovery from stress. Heterostasis came to describe the situation where the demands upon the organism exceed its physiological capacity.

The process of allostatic regulation signifies the recovery and maintenance of internal balance and viability amidst changing circumstances consequential to stress. It encompasses a range of behavioral and physiological functions that direct the adaptive function of regulating homeostatic systems in response to challenges. The allostatic load refers to the set of physiological, psychological, and pathological side effects of the allostatic process, whereas allostatic overload signifies psychobiological collapse, and is associated with a variety of health outcomes systemically.

Type I and Type II Allostatic Responses

The allostatic response encompasses a range of psychobiological outcomes that reflect changes in the

balance between the psychoneuroendocrine and the immune systems. Allostasis overload leads to statistically significant and clinically relevant damage to the organism due to excessive energy expenditure in the response to stress.

Type I

Type I allostasis utilizes stress responses as a mean of self-preservation by means of developing and establishing temporary or permanent adaptation skills. The organism aims at surviving the perturbation in the best condition possible, and at normalizing the normal lifecycle. An example of Type I allostatic response is recurrent aphthous stomatitis (RAS, canker sores), a stress-associated T cell-dependent pathology of the gingival mucosa. RAS lesions are characterized with increased Th1 patterns of cytokine *in situ* (e.g., interleukin (IL)-2). Ongoing work confirms a statistically significant correlation between the clinical incidence of RAS, based on stringent clinical and diagnostic criteria, and scores on a version of the short form-36 health survey questionnaire (SF-36) adapted for dentistry.

Other examples of Type I allostatic response manifested in the oral cavity include teeth grinding: tooth pain that cannot be attributed to carries, cracked tooth syndrome, pulpitis or other circumferential inflammatory process (e.g., gum disease), temporomandibular disorder and pain, and pain at palpation of the masticatory muscles, altered dental anatomy at the coronal surfaces. When the subjects are followed up prospectively, changes in vertical distance of occlusion and the angle of Spee that refers to the curved line that follows the occlusal surface of the posterior teeth of the mandible and is viewed from a sagittal plane are also noted.

Examples of systemic Type I allostatic response include the physiological responses to electromagnetic field. In a paired double-blind study, healthy young adults were exposed to electromagnetic field during controlled sleep. A sharp reduction in secreted melatonin was observed, which was transient and not correlated with any alterations of note in immune responses. The observed twofold increase in IL-2 serum levels failed to alter significantly natural killer cell activity.

Type II

In Type II allostatic load, the stressful challenge is excessive, sustained, or continued, and drives allostasis chronically. An escape response cannot be found. The psychobiological and pathological responses to stress become chronic (e.g., depression, anxiety, hypercortisolemia, and glucocorticoid resistance), with consequential erosion in health and immune surveillance mechanisms.

Oral Lichen Planus

Lichen planus of the oral mucosa (oral lichen planus; OLP) is one example of a Type II allostatic response with evident manifestations of immune suppression in the oral cavity. This form of oral lichenoid lymphocytic mucosal inflammation involves basal cell lysis, and lymphocyte transmigration into the epithelial compartment, and brings about a statistically significant increase in incidence of oral squamous cell carcinoma, which implicates OLP as a premalignant lesion. This chronic inflammatory disorder afflicts 2–3% of the population, and may be in part attributed to aging-associated decrease in the subject's ability to recover from the psychoneuroendocrine-immune changes consequential to stress since OLP is prevalent in individual over 50 years of age. Men are at risk at an earlier age than women (40–49 years with men versus 50–59 years with women). OLP lesions are exacerbated with nonsteroidal anti-inflammatory drugs, antirheumatic drugs, angiotensin-converting enzyme inhibitors, antihypertensive drugs, antibiotics, or β -blockers. These pharmacologic treatments share the commonality of suppressing one or another arm of cellular immunity, suggesting a pathological parallel between OLP lesions and mucositis. The nervous system may play an important role *in vivo* in regulating cellular immune responses in OLP lesions, as suggested by the suggestive alignment of autonomic innervation with lymphocytes (Figure 1). Immune suppression is modulated by sympathetic innervation, and by the cholinergic anti-inflammatory pathway, which inhibits proinflammatory cytokine production and secretion. The relationship between OLP and immune suppression is confirmed by the observation that it appears to result from an abnormal immune response to an unidentified causative agent. Over 75% of invading T cells express the memory phenotype (CD45RO+), the β 1 integrin, CD29+, which renders them essentially sessile. A large proportion of the invading cells also appear phenotypically to be activated Treg (CD25+CD69+). Altered antigenicity of cell-surface epithelial cells causes them to be recognized as immunogenic, in a manner akin to an autoimmune disorder. Human hepatitis C virus (HCV) seems to be a predisposing factor for OLP, and comorbidity of HCV infection with OLP is noted in association with the HLA-Dr6 allele. The genetic propensity for OLP is emphasized by the observation that expression of HLA-Bw57 favors OLP, whereas HLA-Dq1 expression provides resistance against it.

Chronic Pain

A systemic example of Type II allostasis is chronic pain. Patients with fibromyalgia demonstrate altered

Figure 1 Double-label immunohistochemical staining of erosive OLP lesions with CD3 for T cells, and vesicles of acetylcholine transport (VachT; lower panels) and vesicles for monoamine transport (VAMT; upper panels) for autonomic innervation (magnification $\times 100$, oil immersion).

function of β -adrenoceptors. Activation of G-protein coupled receptors, such as the adrenoceptors, leads to an increase in the intracellular level of cAMP. Levels of cAMP serve to assess, albeit indirectly, the functional state of these receptors in immune cells. Patients with fibromyalgia were compared to sex- and age-matched control subjects, and basal and stimulated intracellular cAMP levels were measured, using the β -agonist, isoproterenol (10^{-3} M– 10^{-5} M, following a 5 min preincubation). Basal cAMP levels were shown to be elevated in patients with fibromyalgia (3.02 ± 0.44 pmol/ 10^6 cells, $P = 0.124$), compared to control subjects (2.26 ± 0.39 pmol/ 10^6 cells). Stimulation with isoproterenol at 10^{-3} M significantly increased intracellular cAMP in both groups; but isoproterenol at 10^{-5} M failed to produce this outcome in the patient group ($P = 0.74$), compared to the stimulation by isoproterenol obtained in the control group ($P = 0.012$). Taken together, these data show that patients with fibromyalgia harbor diminished adrenoceptor function in circulating immune cells.

Mucositis

Another example of Type 2 allostasis may be the clinical condition of mucositis. Oropharyngeal mucositis is a common and treatment-limiting side effect of cancer therapy. Oral and gastrointestinal mucositis can affect up to 100% of patients undergoing high-dose chemotherapy and hematopoietic stem cell transplantation, 80% of patients with malignancies of the head and neck receiving radiotherapy, and over 50% of patients receiving chemotherapy. Oral mucositis can be so severe as to lead to the need to

interrupt or discontinue the therapy protocol, and to hinder cure of the primary disease. Mucositis leads to immune suppression, and to an increased risk of local and systemic infection, opportunistic infections, and mortality due to sepsis. It is a critical condition since in 2004 alone, close to 1.5 million Americans were diagnosed with cancer and received some combination therapies for this disease, including surgery, radiation, chemotherapy, immunotherapy, and/or cell transplantation, and mucositis is the principal oral complication from cancer therapies.

The Allostatic Modulation of Immune Suppression

One important regulatory mechanism in allostasis is the interactive neuroendocrine-immune loop. Stress alters the regulation of both the sympathetic and the parasympathetic branches of the autonomic nervous system, and modulates immune suppression. Autonomic activation, and the elevation of hormones, including those produced by the hypothalamic-pituitary-adrenal axis, play a pivotal role in regulating cell-mediated immune surveillance mechanisms, including the production of cytokines that control inflammatory and healing events.

The experience of stress and of traumatic events leads to the release of glucocorticoids, which regulate cellular immune activity *in vivo* systemically and locally: they block the production of proinflammatory cytokines (e.g., IL- 1β , IL-6) and of Th1 cytokines (e.g., IL-2) at the molecular level *in vitro* and *in vivo*, but have little effects upon Th2 cytokines (e.g., IL-4). The activity of the proinflammatory cytokine IL- 1β

is blocked by IL-1 receptor antagonists (IL-1Ra, sIL-1RII) in combination with the soluble IL-1 accessory protein (IL-1R AcP). This results in a long-term beneficial effect in chronic inflammatory diseases. The net effect of challenging immune cells with glucocorticoids is to suppress immune T cell activation and proliferation, while maintaining antibody production. The secretion of glucocorticoids by the adrenal cortex is under the control of the anterior pituitary adrenocorticotropin hormone (ACTH). Immune challenges release proinflammatory cytokines (e.g., IL-1 β , IL-6), which induce hypothalamic secretion of the ACTH inducing corticotropin releasing hormone (CRH). It follows that the consequences of stress are not uniform. The immune-physiological impact of stress may be significantly greater in certain people, compared to others. The impact of stress is dynamic and multifaceted, and the same person may exhibit a variety of manifestations of immune suppression in response to stress with varying degrees of severity at different times. The outcome of stress can be multivalent, and individuals may position themselves along a spectrum of allostatic regulation, somewhere between Type I and Type II allostasis.

Several experimental protocols have been characterized for testing allostasis in animal and human research. Human subjects under stress (e.g., caregivers of elderly patients with dementia and spouses of military personnel in active combat duty) can be subjected to cognitive, sensory, or physiological challenges aimed at studying the allostatic process of immune-physiological adaptation to the challenge in addition to basal states of the stress response.

The Stroop Test

The Stroop color-word interference test is an example of a cognitive challenge that was originally developed in 1935 to examine patterns of cognitive decline. The Stroop challenge is measured as reaction time, and is high in patients with mild to moderate aging-related dementia of the Alzheimer's type (DAT). Patients with more severe dementia show less Stroop interference effect, when the reaction time is adjusted for color naming performance. These observations confirm the need and the importance of partitioning out underlying deficits for the understanding of complex cognitive processes in aging. Principal-components analyses show that disruption of semantic knowledge and speeded verbal processing in certain patients (e.g., patients with neuro-AIDS, patients with DAT) is a major contributor to the incongruent trial. The Stroop challenge is an effective modality for testing the glucocorticoids-cytokine response in healthy

young men and women. Two groups of responders can be distinguished based on salivary and plasma glucocorticoids response to the challenge. The bottom 40% of the responders for cortisol responses to the challenge characteristically manifested significantly higher salivary and plasma levels of IL-6, but lower subjective experience of stress, compared to the high-glucocorticoids responders (top 40 percentile). This confirms that individual variations exist in the response of the glucocorticoids-cytokine axis to mild stress, and that these variations can have potentially adverse health outcomes.

An ongoing study is comparing patients with major depression (*Diagnostic and Statistical Manual of Mental Disorders, 4th edition* (DSM-IV) criteria) with age-, sex-, and ethnicity-matched control subjects for the response on the Stroop test. Preliminary data indicate that the median Raw Color-Word score is 20% higher in the control, compared to the depressed subjects. The median predicted interference score based on Color-Word scores is indistinguishable among healthy and depressed subjects. These data confirm the literature in the substantial differences in percentile position of the median T scores: 66% percentile (depressed patients) versus 42% percentile (healthy control subjects). An important caveat of the Stroop challenge is that color confusion can be inconsistent in certain subgroups of subjects, especially as subjects advanced in age. The Stroop test should not be used for clinical diagnostic purposes, but rather limited as an experimental tool.

The Cold Pressor Test

Another widely used stress paradigm for testing allostasis in human subjects is the cold pressor challenge. The physiological mechanism underlying the response to this challenge, which consists in the immersion of the nondominant hand in an ice bath, involves a response temperature as constriction to blood flow of both superficial and deep tissues of the hand, and associated strong perception of pain. This challenge test is an adequate model to study psychobiological responses to stressful discomfort because cold-induced vasospasms are frequently present in syndromes of chronic pain, but it may have adverse effects in subjects with cardiovascular dysfunctions. Pain latency (e.g., length of time of hand immersion) is significantly shorter in certain populations of patients, such as patients with fibromyalgia and secondary concomitant fibromyalgia, compared to healthy control subjects.

This challenge alters the glucocorticoids-cytokine axis responsivity in healthy young adult men and women, and leads to time-dependent patterns of change in the circadian patterns of salivary IL-6.

Figure 2 Salivary IL-6 response after cold pressor test applied at 10.00 a.m. on healthy volunteers. IL-6 response to stress was more pronounced in female (dashed line) compared to male subjects (solid line) ($P < 0.05$).

The cold pressor test significantly alters salivary IL-6 in control subjects. IL-6 levels were measured at times $t = -5$ min, $t = 0$ min (baseline levels), and $t = 1, 31, 61$, and 91 min postchallenge. Salivary IL-6 rose two- to threefold during the 90 min after cold pressor test. This effect was more pronounced in female compared to male subjects ($P < 0.05$; Figure 2).

The Dexamethasone-Suppression Test

The dexamethasone-suppression test (DST) is a widely used physiological challenge to study the functional response of the glucocorticoids-cytokine axis. Administration of 1–5 mg of dexamethasone (DEX) to healthy subjects in the evening (23.00 h) results in a flattened cortisol plasma level the following morning and day. The cortisol suppression response is an indication of DEX-sensitivity and normal hypothalamic-pituitary-adrenocortical (HPA) response. Significant changes in the migratory properties of circulating CD4⁺ T cells occur in DEX-sensitive control subjects. The use of the DST challenge is in monitoring the glucocorticoids-cytokine response in a variety of patient populations. In DEX-resistant (i.e., no cortisol suppression following DST) subjects, the migratory properties of circulating CD4⁺ T cells are not altered. An intimate relationship is evident between the physiological regulation of the neuroendocrine and cellular immune systems *in vivo* in healthy subjects, compared to patient populations. Stress states can lead to enhanced suppression of cortisol by DEX following the DST challenge, although discrepancies exist among reports. Neither low basal cortisol nor enhanced suppression of cortisol are consistent markers of a posttraumatic stress disorder, for

instance, major depression, or DAT. The lack of reliability, validity, and specificity of the DST as a diagnostic instrument, however, has not reduced the usefulness of this challenge modality to better understand neuroendocrine-immune interactions and the physiological regulation of immune suppression. Another caveat of this paradigm is that it provides a static challenge to the neuroendocrine-immune system: it leads to a shut-off, albeit temporarily, of glucocorticoids flux by acting on its feedback system. In that respect it presents a reflection of the regulatory response, rather than of the glucocorticoid-cytokine axis potential *per se*, as, for example the CRH stimulation test does. Therefore, the DST challenge is a static challenge of glucocorticoids-cytokine responses.

Alcohol and Substance Abuse

Subjects who abuse alcohol or other substances (e.g., cocaine) characteristically exhibit a deregulated pituitary-adrenal axis, elevated cortisol levels, a blunted T cell activation, and consequential immune suppression. Associated is a deregulated distribution of CD4⁺CD62L⁺ cells, which upon withdrawal of alcohol or cocaine abuse, normalizes together with plasma cortisol. Indeed, nicotine and ethanol, at concentrations approximating those found in the plasma of smokers and alcohol abusers, decrease immune surveillance of oral carcinoma by interfering with immune cell-mediated clearance of the tumor target. Significant ($P < 0.05$) diminution of migration, binding, activation, and cytotoxic activity by nicotine when coupled with ethanol contributes to the observed immune suppression.

Experimental Findings

Circulating memory CD4⁺CD45R0⁺ cells in patients with OLP comprise 66% of the circulating leukocyte population, compared to 49% in healthy control subjects, suggesting an imbalance between naïve and memory T cells. Moreover, serum levels of tumor necrosis factor (TNF)- α and IL-6 are significantly elevated in patients with OLP. These patients also exhibit significant alterations in pituitary-adrenal/cellular immune regulation, as do close to 50% of patients with DAT. In these patients, whole saliva can be used for the reliable assessment of neuroendocrine products and cytokines.

Serum, saliva, and cervicular fluid samples were collected for the determination of IL-6 in healthy age-matched control subjects, in patients with DAT, and in their caregivers. Subjects were assessed by a multidimensional evaluation that included collection of demographic data, cognitive function, level of impairment, and assessment of mood states by means of the profile of moods states. Mean IL-6 levels in both plasma and saliva were higher in the group of patients with DAT, compared to the caregiver and control subjects. Crevicular fluid determinations were unreliable due to the small volume collected. Saliva and plasma IL-6 levels were well correlated. Profiles of moods states scores were significantly higher in the caregiver group (54.80 ± 65.45 ; -16 – 166), compared to the patient group with DAT (39.6 ± 50.5 ; 6 – 129), and the control subjects (9.4 ± 12.1 ; -26 – 2) (Wilcoxon, $P < 0.05$). Caregivers showed lower emotional well-being and more emotional stress than patients and healthy noncaregiver controls.

T Cell Anergy and Apoptosis

T cell activation can lead to the proliferative response. Alternative pathways can attenuate or prevent the response of T cells, and lead to anergy (i.e., absence of response) or apoptosis (i.e., spontaneous programmed cell death), and consequential immune suppression.

T cell stimulation by triggering through the T cell receptor (TcR) in the absence of CD28-mediated costimulatory signals induces unresponsiveness to further stimulation in T cells, a phenomenon known as anergy. Anergic T cells do not produce IL-2 when challenged, and are defective in their ability to upregulate protein binding and transactivation at two critical IL-2 DNA enhancer elements: NF-AT (nuclear factor of activated T cells; a sequence that binds a heterotrimeric NFATp, fos, and jun protein complex), activator protein-1 (AP-1; that binds fos and jun heterodimers), the Janus tyrosine kinases (Jak), and the signal transducers and activators of transcription

(Stat) act as key regulatory components. The impaired DNA-protein interactions in anergic T cells is related to poor expression of the inducible AP-1 family members c-fos, fosB, and junB, attributable, at least in part, to a selective block in the expression of the AP-1 Fos and Jun family members in anergic T cells. Ligation of CD28 results in its phosphorylation and subsequent recruitment and activation of phosphatidylinositol (PI)3-kinase. Pharmacological and mutational analysis data show that disruption of PI3-kinase association with CD28 is neither necessary nor sufficient for costimulation of IL-2 production. T cell anergy also involves transcription regulators.

Calmodulin

Calmodulin (CaM) is an intracellular Ca²⁺-binding protein that mediates many of the effects of Ca²⁺. CaM binds to Fas directly and identifies the CaM-binding site on the cytoplasmic death domain (DD) of Fas. Fas (APO-1/CD95) is a cell-surface receptor that initiates apoptotic pathways, and its cytoplasmic domain interacts with various molecules suggesting that Fas signaling is complex and regulated by multiple proteins. The processes of T cell anergy and apoptosis are intertwined and act together to play critical role in immune suppression.

The Apoptosis Process

The process of apoptosis is a complex network, with different nodes connected by physical interactions of critical domains, including the caspase recruitment domains (CARDs); death effector domains (DEDs); DDs; BIR (baculovirus inhibitor of apoptosis proteins (IAP) repeat) domains of IAPs; Bcl-2 family proteins; caspase protease domains; and endonuclease-associated CIDE (cell death-inducing DNA fragmentation factor (DFF)45like effector) domains. Apoptotic cell death is thus a multifaceted process, whose initial signal is triggered in part by members of the TNF receptor superfamily, including Fas. When Fas interacts with the Fas-ligand, transmembrane signals are initiated through the associated FADD/MORT-1 motif, which interacts with caspase-8. Up to 10 caspases have been identified to date, which have been numbered based upon the chronological order of publication of their respective cDNAs. Active caspases are released from cleavage from the proenzyme into a larger peptide (17–22 kD) and a smaller peptide (10–12 kD) that associate to form the active enzyme in cells undergoing apoptosis. Caspase-8 possesses two motifs near the 5'-terminal that associate with FADD, referred to as the death

effector domain. Activated caspase-8 in turn activates other caspases, and acts directly on mitochondrial permeability and metabolism.

Mitochondria

Mitochondria are involved in apoptosis through release of soluble molecules, such as bcl-2 that is normally situated in the outer mitochondrial membrane near the inner–outer membrane contact sites where permeability pores form. The action of bcl-2 is to protect against apoptosis by preventing the opening of these pores and release of a 50-kD protease and cytochrome C. Additional events involve changes in the plasma membrane and translocation of phosphatidyl-serine from the inner to the outer aspect of the membrane, which can be reliably detected by its high affinity to the Ca^{2+} -dependent phospholipid-binding protein, Annexin-5 (35–36 kD). Signals reach the nucleus for activation of nucleases and degradation of chromosomes into nucleosomal subunits. These metabolites are detected either as fragments of increasing length on an agarose gel or as cytoplasmic content of nucleosomal proteins.

β -Amyloid

Case in point, the peptide found in the neural plaques that characterize Alzheimer's disease, β -amyloid, significantly modulates T cell-mediated immunity.

The 1–42 β -amyloid peptide leads to T cell anergy, and impairs the generation of CD4+CD25+ and CD8+CD25+ Treg by up to 25%. This effect is attributable to the 28–35 portion of the peptide, the same that is responsible for impairing the maturation of T cell *in vitro*. The peptide also induces apoptotic cell death of healthy human T cells, as monitored by augmentation of cytoplasmic oligonucleosomes following treatment with β -amyloid, and a over three-fold induction of caspase 3 (Figure 3).

A New Strategy: Molecular Cartography

Molecular cartography is the science of recognizing and identifying the multifaceted and intricate array of interacting genes and gene products that characterize the function and specialization of each individual cell in the context of cell–cell interaction, tissue and organ function. The relevance of molecular cartography pertains to every domain of physiology, including immunity.

Molecular cartography provides the fundamental knowledge and understanding of the genomic, the proteomic, and interactomic processes that regulate the emergence, stability, and function of immune cell populations, and the mechanisms by which the psychoneuroendocrine system regulates immunity. It produces new fundamental knowledge with respect to the processes that regulate immune suppression.

Figure 3 Caspase 3 induction in healthy human T cells exposed to β -amyloid peptide (1–42) for 48 h. Upper panel shows untreated (control) cultures. Lower panel shows β -amyloid-treated cultures. β -amyloid stimulated over threefold induction of caspase 3.

Class of white blood cells that kill virally infected or tumor cells.

A major hormonal stress response system in the body that regulates the secretion of cortisol, which mobilizes glucose into the bloodstream.

The reduction of the activity of components of the immune system.

A class of white blood cells that attacks transformed or dying cells, such as tumor cells.

Interacting effects of the central nervous system on immune function.

A precursor protein that is the source of adrenocorticotrophic hormone, which triggers cortisol release, and of endogenous opiates

Cancer can be understood as, among other things, a series of stressors: the diagnosis, arduous treatments, fears of death, and changes in social and physical environment. For example, as many as 80% of breast cancer patients report significant distress during initial treatment. Estimates of the prevalence of

psychiatric disorders among newly diagnosed cancer patients has ranged from 30–44%, and 20–45% exhibit emotional morbidity 1–2 years later. Although the majority of cancer patients do not have a psychiatric diagnosis, for those who do depression is the most common one, and the vast majority experience the diagnosis of cancer as a major stressor. Up to 10% have severe maladjustment as long as 6 years later. Thus, cancer is a disease that causes considerable psychological stress.

Cancer is largely a disease of aging; it is rare below the age of 50 and increasingly common with advancing age. To the extent that abnormalities of the endocrine stress response system, the hypothalamic-pituitary-adrenal axis (HPA), increase with age and affect cancer progression, their impact should increase with advancing age due to a greater likelihood of abnormality and a higher prevalence of disease. The bulk of cancer research has productively focused on the pathophysiology of the disease, emphasizing tumor biology, especially tumor characteristics such as DNA ploidy and estrogen/progesterone receptor status as predictors of disease outcome at the expense of studying the body's psychophysiological reactions to tumor invasion. These reactions are mediated by brain-body mechanisms, including the endocrine, neuroimmune, and autonomic nervous systems. Although a large portion of the variance in any disease outcome is accounted for by the specific local pathophysiology of that disease, some variability must also be explained by host resistance factors, which include the manner of response to the stress of the illness. For example, in a series of classic experiments in animals, Riley showed that crowding accelerated the rate of tumor growth and mortality. In a recent authoritative review of human stress literature, McEwen documented the adverse health effects of cumulative stressors and the body's failure to adapt the stress response to them. The activation of the HPA axis is an adaptive response to acute stress, but over time, in response to cumulative stress, the system's signal-to-noise ratio can be degraded so that it is partially on all the time, leading to adverse physiological consequences, including abnormalities of glucose metabolism, hippocampal damage, accumulation of abdominal fat, and depression. Abnormalities of HPA axis function, including glucocorticoid receptor hypersensitivity, have also been found to be associated with posttraumatic stress disorder. Thus, adverse emotional events, ranging from traumatic stressors to cumulative minor ones, are associated with HPA axis dysregulation. Persistently elevated or relatively invariant levels of cortisol may, in turn, stimulate tumor proliferation via differential gluconeogenesis in normal and tumor tissue, the activation of hormone receptors in tumor,

or immunosuppression. Glucocorticoid dysregulation may be associated with other stress-related endocrine and immune dysfunction that could have consequences for host resistance to cancer progression.

Stress Reactivity and Disease Progression

Reactivity to stressors involves not only the initial response but the system's ability to reset itself after stress. Older organisms seem to reset themselves after a stressor less readily, leaving stress-responsive systems more tonically upregulated for longer periods of time after the cessation of the stressor. Cancer affects older people particularly, and chronic disease-related stressors are perhaps likely to further decrease the flexibility of stress response mechanisms. Sapolsky and colleagues found that stressed older animals had not only persistently elevated cortisol levels after the stress was over but also much more rapid growth of implanted tumors. This finding was confirmed in a study that also identified the suppressive effects of stress hormones on natural killer (NK) cells as one potential mediator of the effect. It may not be so much the magnitude of stress-induced elevation of corticosteroids that is important in cancer outcomes as the duration or persistence of the elevation. These findings are particularly relevant because there is evidence that persistent elevations of cortisol, as measured by slower rates of cortisol decline throughout the day, have been associated with both shorter cancer survival and the suppression of NK cells. These lymphocytes, identified with CD56 cell surface markers, do not attack specific antigens but rather destroy transformed or dying cells, such as cancer cells. The number and killing activity of these NK cells have been found to be associated with the progression of breast cancer. As the disease progresses, NK activity declines and, conversely, declining NK activity and counts predicts breast cancer progression.

Stress Hormones and Cancer Progression

Mechanisms have been proposed whereby the neuroendocrine correlates of stress may promote neoplastic growth. Stress hormones may suppress immune resistance to tumors or act via differential effects on gluconeogenesis in healthy versus tumor cells. Tumor cells may become resistant to the catabolic action of cortisol, which inhibits the uptake of glucose in numerous cell types. In such cases, energy would be preferentially shunted to the tumor and away from normal cells by cortisol. Several studies have found an association between the stress-related elevation

of glucocorticoids and more rapid tumor growth in animals. Another hypothesis suggests that HPA axis hormones may promote the expression of breast cancer oncogenes due to activation of proopiomelanocortin (POMC) genes by corticotropin releasing hormone (CRH). The POMC promoter has homology with POMC transcription factors that bind to human MAT-1 breast cancer oncogenes. Also, fasting insulin levels have been found to predict subsequent mortality from breast cancer, whereas levels of insulin-like growth factor binding proteins predict recurrence but not mortality. Thus, there are a variety of means by which depression-related abnormalities in HPA axis function could affect the rate of cancer progression. One leading hypothesis is an association between HPA axis and immune dysfunction because glucocorticoids are potentially immunosuppressive.

Stress and Tumor Immunosurveillance

Although some aspects of antitumor immune responses are still controversial, there is now ample evidence to show that under certain conditions the immune system plays a crucial and protective role by detecting and eliminating tumors. Recently, Dunn et al. introduced the concept of tumor immunoediting, which hypothesizes that the immune system plays a critical role not only in detecting and eliminating tumors but also in shaping the extent of immunogenicity or nonimmunogenicity of tumors that ultimately escape immunosurveillance and result in clinically observable malignant disease. Evidence for the immunosurveillance hypothesis comes from (1) studies that show an increased incidence of virally induced cancers, such as Kaposi's sarcoma and non-Hodgkin's lymphoma, in patients undergoing immunosuppressive treatments; (2) studies of patients with immunodeficiency diseases; and (3) studies using selective cytokine- or leukocyte-deficient mice. However, immunosurveillance is also thought to play an important role in the elimination of cancers that do not have a viral etiology (e.g., malignant melanoma, non-Kaposi's sarcoma, and lung tumors), and higher incidence ratios for these cancers are observed in immunocompromised hosts.

All major leukocyte subtypes, including macrophages, granulocytes, NK cells, helper and cytolytic T cells, and B cells, are thought to play a role in immune surveillance. However, under certain conditions, regulatory/suppressor leukocytes such as subsets of CD25+ and CD4+ T cells and natural killer T (NKT) cells, may inhibit antitumor immune responses. Specific cytokines and chemokines are thought to exert direct and indirect protective (suppression of tumor development and progression)

as well as harmful (promotion of tumor growth and metastasis) effects. Moreover, in contrast to protective, regulated, antitumor immune responses, dysregulated or chronic immune responses directed against pathogens or self-antigens can induce or exacerbate tumorigenesis through chronic tissue damage and activation.

Prolonged or chronic stress has been shown to affect most immune parameters thought to be important for tumor surveillance. Therefore, stress may affect immune function and susceptibility to cancer in several different ways. First, in general, chronic stress and stress hormone exposure have been associated with the suppression of NK activity, T-cell responses, and cell-mediated immune reactions; decreased telomere length and telomerase activity in circulating leukocytes; increased tumor metastases; enhanced growth of transplanted tumors; and increased tumor number, size, and density of skin cancer (squamous cell carcinoma). Second, stress may also suppress antiviral immune responses. The suppression of immunity to transforming viruses could significantly enhance the risk of tumor formation and progression. Third, chronic stress may contribute to immune dysregulation and promote or sustain chronic pro-inflammatory states that, in turn, induce or exacerbate cancer. Fourth, glucocorticoids are potentially immunosuppressive, so the effects stress and hypercortisolemia may include functional immunosuppression as well, as has been shown extensively in animals and for which there is a growing body of evidence in humans. This, in turn, could influence the rate of cancer progression.

Psychosocial-Biobehavioral Intervention and Cancer

Understanding how psychosocial factors such as stress can suppress protective immune function may help in the design of psychosocial-biobehavioral interventions that may buffer against stress- and depression-induced effects, thereby improving patient quality of life and potential survival. Five of eleven published randomized trials demonstrate such an effect. The principles of such stress management techniques include helping cancer patients construct a new network of social support; encouraging the expression and management of the range of emotions typical of such stress-inducing illness, including anger, fear, and sadness; helping people face their fears of dying and death; and reordering life priorities. Other helpful components include improving social relationships; enhancing doctor-patient communication; educating the patient about coping skills, the disease, and its treatment; and teaching anxiety

and pain management techniques. Such interventions clearly improve patient quality of life and may have a positive effect on survival time via effects on endocrine, circadian, and immune physiology.

Causes of Immune Aging
Aging and Infections

Glossary

<i>Autoantibody</i>	Immunoglobulin whose specificity is directed at self.
<i>C-reactive protein</i>	A small protein of the pentraxin family, secreted and catabolized only by the hepatocytes (liver parenchymal cells). It was named for its ability to bind with pneumococcal C-polysaccharide. Its synthesis is under transcriptional control, regulated by pro-inflammatory cytokines (especially interleukin 6), and it is one of the proteins that characterize the acute phase response.
<i>Cytokine</i>	A small protein or glycoprotein that generally acts locally to alter cell behavior or function. Cytokines may be considered locally acting hormones. The major classes of cytokines are interleukins, interferons, and tumor necrosis factors.
<i>Endotoxin</i>	Lipopolysaccharides from the walls of gram-negative bacteria that can activate lymphocytes and mononuclear phagocytes.
<i>Epstein-Barr virus</i>	A herpesvirus that, after a primary infection, remains latent in B lymphocytes and may be reactivated at some later time.
<i>Lymphocyte</i>	A small cell derived from the bone marrow that, after appropriate processing and maturation, can participate in specific immune responses. B lymphocytes (B cells) further differentiate into plasma cells, which secrete immunoglobulin (antibody).
<i>Monoclonal antibody</i>	An immunoglobulin of a single specificity produced by an expanded clone of plasma cells.

Mononuclear phagocyte

A cell of bone marrow origin, larger than a lymphocyte, that can phagocytose foreign material and present it to lymphocytes to bring about an immune response. Examples are monocytes, macrophages, and Kupffer cells.

Immune Systems

Two interactive immune systems are recognized: innate (natural) immunity and acquired (adoptive or specific) immunity. Innate immunity comprises polymorphonuclear leukocytes (neutrophils, eosinophils, and basophils), natural killer (NK) cells, and mononuclear phagocytes, and it uses the complement cascade as its main soluble protein effector mechanism. It also uses numerous recognition molecules, including C-reactive protein (CRP), serum amyloid protein (SAP), and mannose-binding protein (MBP). These molecules have been selected during evolution to bind carbohydrate structures that do not occur on eukaryotic cells and so differentiate potentially harmful invaders from innocuous self.

Acquired immunity employs several subtypes of lymphocytes and uses antibody as its effector protein. Antibody and the T-cell receptor (TCR) are the recognition structures. B lymphocytes can recognize protein, carbohydrate, and simple chemical structures, whereas T lymphocytes seem to recognize only peptides. Clones of lymphocytes with receptors of sufficient affinity are triggered by antigen to proliferate and differentiate into the various effector cells: T-helper (Th) cells, cytotoxic T cells, suppressor T cells, and plasma cells (which secrete antibody).

After an immune response subsides, specific antibody often persists in the blood for many years and even decades. This implies that humoral effector cells (plasma cells) persist and continue to secrete antibody. In contrast, the antibody response at mucosal surfaces is generally short-lived (a few months to a year). Effector T cells do not persist for very long, but antigen-specific clones remain expanded as memory lymphocytes, which can differentiate quickly into effector cells if the antigen is encountered again. In general, memory responses are most effective in protecting against systemic infections (e.g., measles, mumps, poliomyelitis, and smallpox). Localized infections at mucosal surfaces (e.g., rotavirus, respiratory

syncytial virus, and rhinovirus) can recur before memory lymphocytes can differentiate into effector cells, although the subsequent episodes of disease are usually less severe.

The flexible nature of specific immunity poses the problem of differentiating innocuous (self) antigens from harmful ones, a problem that innate immunity does not have. One way of overcoming this is to delete potentially self-reactive clones during maturation in the thymus (for T cells) and at a yet unknown site for B cells. Further specificity is assured by interactions with innate immunity. For T cells, antigen presentation is the critical step. The uptake of antigen into antigen-presenting cells (e.g., mononuclear phagocytes and dendritic cells) is determined by the presence of carbohydrate moieties that are recognized by innate immunity. For B cells, the interaction with innate immunity seems to be their membrane receptors for the C3d component of complement, which is found in association with CD19. CD19 is needed for antibody production for T-cell-dependent antigens and amplifies signaling after the antigen binds membrane immunoglobulin. Covalent binding of C3d to microbial carbohydrate structures facilitates this process. Different pathogens require different types of response for their elimination: type 1 responses (characterized by dependence on macrophages for phagocytosis and intracellular killing) and type 2 responses (macrophage independent, relying on non-cytotoxic antibodies, mast cells, and eosinophils). Th cells are required for both types of response, but these exist as two subtypes, called Th1 and Th2. Th1 cells produce interleukin (IL)-2, IL-3, tumor necrosis factor (TNF)- α , and interferon (IFN)- γ , and this pattern of cytokines promotes type 1 responses. Macrophages are activated and B cells are switched to IgG1 production (in humans), which binds macrophage Fc receptors and activates complement, both of which promote phagocytosis. Activated macrophages produce IL-12, TNF- α , and IFN- γ . This pattern of cytokines (especially IL-12) induces the activation and proliferation of NK cells, the differentiation of naïve T cells into Th cells, and the expression of the Th1 phenotype.

Th2 cells promote type 2 responses. Th2 cells require IL-4 to prime naïve cells. Once activated, they produce IL-3, IL-4, IL-5, IL-6, IL-10, and IL-13. This pattern of cytokines leads to the growth and activation of mast cells and eosinophils. It also switches B lymphocytes to produce IgG4 (and IgE) and inhibits macrophage activation. This pattern of response is typical of helminth infections, and it may also be important for the downregulation of type 1 responses.

Pattern of Immune Aging

Of all body systems, the immune system is probably the best understood, and studies of it can be traced to the early part of this century (and even earlier). Perhaps the first publication was by Peter Ludwig Panum, a Danish physician best remembered for the discovery of endotoxins. He reported an outbreak of measles in the Faroe Islands in 1846. The islands had been free of measles since the previous epidemic in 1781. The reported outbreak affected 75–95% of the population, although “of the many aged people still living on the Faroes who had had measles in 1781, not one was attacked a second time.”

The classic view of immune aging (immunosenescence) is of an immunodeficiency state that predisposes the host to infectious diseases and possibly also neoplasms. The state is often attributed to the involution of the thymus gland and is thought to be characterized by the decreased proliferation of T lymphocytes and impaired Th activity, which lead to impaired cell-mediated and humoral responses to T-cell-dependent antigens. B-lymphocyte numbers and function (antibody production) seem to change little, although in the intact organism antibody titers to a variety of vaccine antigens are generally reduced. Paradoxically, there is an increased incidence of autoantibodies (inevitably of low titer) and benign monoclonal B-lymphocyte proliferations with monoclonal antibody production. Interestingly, older people in Japan have a very low incidence of these benign monoclonal proliferations, suggesting the importance of genetic factors in outbred populations such as humans.

With the discovery of cytokines and their regulatory importance for many cell types (including the cells of the immune system), new insights have emerged concerning the mechanisms underlying immunosenescence. The patterns of cytokine secretion by T lymphocytes from young and old mice clearly differ. In the young, IL-2 and IL-4 predominate, whereas in the old it is IL-10 and INF- γ . The young pattern also characterizes Th1 responses and the old pattern the Th2 responses. It is also known that naïve T cells (which have never encountered antigen) exhibit Th1 responses and that memory T cells (which persist after antigen exposure) exhibit Th2 responses. Memory T cells are known to accumulate during aging. Furthermore, the change in the balance of Th1-to-Th2 responses can be partially reversed by thymic hormones and the steroid dehydroepiandrosterone. However, the altered Th1–Th2 balance is not explained simply by the accumulation of memory T cells. Th1 function clearly declines during aging. For example, old mice are unable to develop

tolerance to Staphylococcal enterotoxin B and die from shock, whereas young mice develop a tolerance and do not die. Thus, thinking has changed from the classic view of immunosenescence toward a view based on immune dysregulation, predominantly the disturbed balance of Th1–Th2 responses, a change that also appears to occur in humans. Increased Th1 and reduced Th2 responses would be expected to predispose to infections, but what causes this change?

Causes of Immune Aging

Clearly, the accumulation of memory T cells could explain some of the change, but it cannot account for it entirely. In outbred populations such as humans, there are genetic polymorphisms in the promoter regions of many (if not all) cytokine genes and the selective survival of particular genotypes could play a part but cannot explain the change in an inbred strain. One intriguing suggestion is that inflammation could be a significant cause.

Inflammation

Of all inflammatory cells, macrophages have been given the closest scrutiny. When stimulated, they secrete a variety of inflammatory mediators, including the pro-inflammatory cytokines IL-1, IL-6, and TNF- α . *In vivo* administration of endotoxin to mice induces the production of TNF- α , IL-1, IL-6, and INF- γ , and the response is much exaggerated in old animals. IL-6 is produced constitutively, and circulating levels are higher in the older (mice and humans) subjects than in the young. Treating old mice with antibodies to IL-6 reduces the magnitude of the Th2 pattern. IL-6 is known to orchestrate the so-called acute phase response, including the production of CRP in the liver. CRP is familiar to most readers as a clinical marker for inflammation and may itself exacerbate tissue damage, but why is the constitutive production of IL-6 higher in the old? What signals might be present in them that may not be present in the young?

Aging as a Pro-inflammatory State

The evidence presented in this article argues strongly for an exaggeration of the macrophage component of inflammation. Is there evidence that other inflammatory cells are similarly affected? The cell type that arrives earliest at a site of infection or tissue damage is the neutrophil. The effects of aging on neutrophil function are controversial – some *in vitro* studies show impaired function, whereas others show no impairment. In contrast, *in vivo* studies are unambiguous in showing that the neutrophil influx is greater

in the old. One interesting study in mice with experimental pneumonia revealed a greater neutrophil influx in the old, associated with a higher death rate. This finding is entirely consistent with the author's studies of endotoxin administration to aged rats. Older humans also seem to experience such exaggerated inflammatory responses. For example, the adult respiratory distress syndrome and the systemic inflammatory response syndrome are both largely conditions of the old, and both are characterized by unrestrained inflammation. More controlled studies of experimental cutaneous wound healing in humans also show more rapid and more marked neutrophil influx into the site of injury in older subjects. This leads to high collagen turnover and probably slower wound healing but a restoration of dermal architecture (unlike the disorganized collagen deposition in the young) and a cosmetically more appealing end result. Interestingly, this effect can be reversed by prior treatment with estrogen, at least in older women.

Replicative Senescence

Studies on aging murine and human T-cell clones have shown that a population remains with normal responses in the midst of a much larger population with reduced responses, including reduced proliferation. It has been suggested that this might be an *in vivo* manifestation of replicative senescence (Hayflick limit), thought to occur in other types of aging cells *in vitro*. *In vitro*, such senescent cells fail to express CD28, have shortened telomeres, and are clearly memory cells (and express CD45RO). *In vivo*, there is known to be a decline in CD28+, with telomere shortening as well as a minimal proliferative capacity. The majority of these CD28+ are CD8+. Almost identical changes have been documented in acquired immunodeficiency syndrome (AIDS), in which they may be due to prolonged or repeated episodes of human immunodeficiency virus (HIV)-induced T-cell proliferation.

Reactivation of latent viruses It has been proposed that the accumulation of T cells showing the characteristics of replicative senescence of aging occurs by a similar mechanism to that in AIDS, that is, periodic or chronic restimulation of memory T cells. The idea that immune aging might result from the presence of immune activators is not new. Because such episodes of antigenic stimulation might also induce nonspecific T-cell replication (bystander replication), their effect on the integrity of the aging immune system may have been underestimated. Candidates for such chronic restimulation may include latent viruses

such as the Epstein–Barr virus (EBV) or pathogens with epitopes that are cross-reactive with self-antigens present on T cells (e.g., influenza A). The consequence of bystander lymphocyte senescence may be that fewer functional CD8⁺ T cells may be available to combat infections and cancer. EBV is acquired asymptotically in childhood, as a symptomatic disease in adolescence (glandular fever and infectious mononucleosis), or as a new infection in old age. Of the seven EBV seroepidemiological studies that include older people, all have shown the highest titers of antibodies in the old. Although this suggests that reactivation does indeed occur in old age, the symptoms of glandular fever are absent. EBV can also be detected in saliva. Twenty percent of people over the age of 50 excrete the virus, but the prevalence of viral shedding in a truly aged population is unknown. Immunosuppression is known to increase the prevalence of virus shedding to over 90%. Symptomatic reactivation has been associated with Hodgkin's disease, nasopharyngeal carcinoma, oral hairy leukoplakia, lymphocytic interstitial pneumonia, and B-cell lymphoproliferative disease. EBV reactivation syndromes have never been investigated in older people, and morbidity could arise from the inappropriate production of cytokines (particularly in people with certain promoter region polymorphisms) and the premature onset of replicative senescence.

Aging and Infections

When an organism arrives at a potential portal of entry into the host (usually an epithelial surface), three outcomes are possible: the organism is eliminated, the organism proliferates successfully but fails to invade tissues, or tissue invasion occurs. For most organisms, tissue invasion is a *sine qua non* for infection, although some induce changes in the host predominantly through the elaboration of toxins (e.g., cholera). When tissue invasion occurs, an acute inflammatory response is triggered, and it is usually by the recognition of the systemic consequences of this that we diagnose infections. The host feels unwell, anorexic, and somnolent (thought to be induced mainly by IL-6). The hypothalamic thermostat is reset to a higher level and the host feels cold and attempts to raise the core temperature to this new level (fever). This is achieved by reducing heat loss by vasoconstriction and behavioral means (e.g., extra clothes) and by shivering. The metabolic rate is increased, although this is a much more important mechanism for small mammals than for large ones. Uncontrolled studies suggest that the old often fail to produce a fever response, but more careful studies suggest that this may not be the case. First, care must be taken

with the measurement of body temperature. Using inadequate instruments at sites of heat loss (e.g., mouth or axilla) almost guarantees the failure to detect fever. The rectum and the tympanic membranes are more reliable sites, and electronic and infrared thermometers equilibrate much faster than mercury-in-glass ones. Second, the ambient temperature may be too low for the host to overcome, and the core temperature may rise into the febrile range only in a warm environment. Finally, experimental studies with several pyrogenic cytokines suggest that the hypothalamic thermostat of the old may be desensitized (dose–response curve shifts to the right) but that the maximal response is unaffected by aging. Another important sign of infection is the detection of an elevation in the circulating white blood cell count (mainly neutrophils), and there is no evidence that aging impairs this response. Likewise, older people also increase the levels of CRP in a pattern indistinguishable from similarly infected young people.

Comorbid factors such as malnutrition, glucocorticoid administration, and so forth can certainly impair host responses and do so in both young and old. Further, diseases at other sites are common in the old and may obscure the characteristic findings of infections. Age-related changes in several body systems predispose to more general types of presentation, known as the giants of geriatrics: immobility, falls, delirium, and incontinence. Thus, it is important to consider infection as a possible diagnosis in any older person whose condition changes acutely, whether the characteristic features are present or not.

Are Older People Predisposed to Acquire Infections?

This question is very difficult to answer. Theoretically, age-related immune changes could well predispose to acquiring infections, but they are not the only factors involved. To acquire an infection requires exposure to a potential pathogen, and this exposure is greatly dependent on environmental and lifestyle factors. For example, people who do not practice unprotected sexual intercourse and who have never had a blood transfusion are highly unlikely to be exposed to HIV. To acquire a common cold or influenza requires contact with an infected person; those living a solitary lifestyle, not traveling on crowded public transport, and not visiting places where people congregate (school, work, football matches, and so forth) may have considerably reduced risks of exposure to potential pathogens. However, those living in relatively closed environments (e.g., nursing homes) may be at an extremely high risk if a potential pathogen is introduced (e.g., tuberculosis, methicillin-resistant *Staphylococcus aureus*, *Clostridium difficile*,

or rotaviruses). Very few hard data exist that make any direct comparisons across age groups. Perhaps the most reliable data come from the American National Health Interview Surveys. These have shown the community-dwelling aged to be at a considerably lower risk of developing colds or influenza than any other age group and at only a modestly increased risk of developing pneumonia. What is not in doubt is that, once infected, the old will be sicker and more likely to die.

level by the expression of FoxP3, the P3 member of the first forkhead-box (FOX) transcription factor, which functions as a transcriptional repressor at the nuclear factor for activation of T cell (NFAT)/activating protein (AP)-1 sites in cytokine gene promoters, and functionally Treg act to impair proliferative and IL-2 production responses, thus blunting T cell-mediated immunity.

A family of seven known cytoplasmic proteins, the suppressor of cytokine signaling, which modulate cytokine-mediated regulation of immunity.

Glossary

Immunological synapse Complex assemblage of rafts that integrates the signaling cascades for the amplification and regulation of T cell activation.

Rafts Microdomains determined by and anchored to the cytoskeleton of T cells, and important in coordinating the signaling response in T cell-mediated immunity.

Regulatory T cells (Treg) Characterized phenotypically by the expression of the α chain of the interleukin (IL)-2 receptor, CD25, at the molecular

level by the expression of FoxP3, the P3 member of the first forkhead-box (FOX) transcription factor, which functions as a transcriptional repressor at the nuclear factor for activation of T cell (NFAT)/activating protein (AP)-1 sites in cytokine gene promoters, and functionally Treg act to impair proliferative and IL-2 production responses, thus blunting T cell-mediated immunity.

Immunity confers protection of the organism against pathogens. Innate immunity concerns humoral (e.g., complement) and cellular events (e.g., natural killer cells) that do not require priming by antigens. Antigen-specific immunity addresses that branch of cellular (e.g., cytotoxic T lymphocytes and plasma B cells) and humoral immune surveillance (e.g., cytokine patterns, immunoglobulins) that depends upon the phenotypic (e.g., memory CD4+ T cells, CD4+CD45RO+, and B cells) and functional stage maturation of

lymphocytes following presentation of the antigen by the major histocompatibility complex (MHC).

Immunity comprises important innate and adaptive immune responses. Viruses, bacteria, or classical parasites all probe the limit of immunity, and of the three basic parameters of immunology – specificity, tolerance, and memory. The practical specificity repertoire of T and B cells is probably in the order of 10^4 – 10^7 specificities expressed by T cells or by neutralizing antibodies. Tolerance is best defined by rules of reactivity to eliminate infections while avoiding destruction of normal cells by complete elimination of T cells that are specific for antigens persisting in the blood and lymphohemopoietic system. Induction of a T-cell response is the result of antigens newly entering the lymph nodes or the spleen, initially in a local fashion and exhibiting an optimal distribution kinetics within the lymphohemopoietic system. Antigens that stay outside lymphatic tissues are generally immunologically ignored. Immunity is regulated by antigen dose, time, and relative distribution kinetics. Memory relates to the host's resistance following a second exposure to the same agent, and it correlates with antigen-dependent maintenance of circulating antibody titers, and with T-cell responses.

In a previous article, we discussed innate and antigen-dependent immunity in general. Recent research developments have established the central role of T cells in regulating immune surveillance. This article focuses on novel knowledge pertaining to T cell-mediated immunity. The vast domain of autoimmunity is not addressed in this article.

T-Cell Proliferation

T lymphocytes, 70–80% of the peripheral blood mononuclear cells, express the cluster of differentiation (CD)-3, but lack CD14 (i.e., monocyte-specific) and CD20/21 markers (i.e., B cell-specific). CD3 is proximal to the T-cell receptor (TcR), constituted by the α and β chains in circulating T cells, and by the γ and δ chains in the mucosal lymphoid tissue. T cells are stimulated *in vivo* via TcR, and *in vitro* by immobilized anti-CD3 antibody and the CD28 co-stimulus, lest the cells fail to proliferate and enter anergy, a state of stunted cell activation and proliferative capability.

Rafts

Lipids and proteolipids in the T-cell membrane are organized into rafts, microdomains determined by and anchored to the cytoskeleton. Rafts compose the immune synapse, a complex assemblage that integrates the signaling cascades. The synapse amplifies and regulates the activation of T cells. The assembly

of the immune synapse at the antigen-presenting site depends on the interactions between rafts and the actin cytoskeleton, which controls the coalescence of smaller raft components into the larger immune synapse complex to integrate cellular responses to diverse signals. Phosphoinositide 1,5 bisphosphate (PIP2) regulates raft cytoskeletal structure by regulating proteins that control actin dynamics. Upon stimulation, PIP2 is converted to PIP3 and diacylglycerol. Ceramide mediates this clustering and insertion into the lipid bilayer by acetylation motifs.

Raft constituents change, define and determine the process of T cell activation, and maturation, as for instance the increase in raft-associated glycosphingolipid GM1. Compared to resting (CD69–CD25–) or naïve T cells (CD45RA+), activated (CD69+CD25+) or memory T cells (CD45RO+) have significantly higher GM1 levels. CD3/CD28 stimulation promotes recruitment into rafts of the Src family kinase Lck, which co-localizes in rafts with glycosylphosphatidyl inositol (GPI)-anchored proteins, the adaptor protein LAT and Ras, but not with nonraft membrane proteins (e.g., protein tyrosine phosphatase, CD45). β -endorphin, which is released during stress and which significantly impairs PIP2 metabolism and associated kinase activity during T-cell activation, may alter rafts structure.

Membrane Markers of Cell Activation

T-cell activation results in change of morphology to blast cells with large cytoplasm-to-nucleus ratio, loss of CD62L, the peripheral lymph node homing receptor, expression of the integrin lymphocyte function-associated antigen (LFA)-1, and replacement of CD45RA with the maturation marker CD45RO. Activated T cells express CD69, the activation inducer molecule, a very early activation antigen (MLR-3, Leu-23), several hours before CD25 (Figure 1). CD69, a member of the natural killer cell family of signal-transducing receptors, is a type II transmembrane glycoprotein with a C-type lectin-binding domain in its extracellular domain. CD69 controls and regulates the expression of the interleukin (IL)-2 gene by its action downstream to the nuclear factor for activation of T cell (NFAT) and activating protein (AP)-1 transcription complexes.

Following expression of CD69, the IL-2 and CD25 genes are activated. CD25, the chain of the IL-2 receptor is expressed in high density on the cell membrane. Rafts regulate immune signaling in part by segregating cytokine receptors. The β chain of the IL-2 and the IL-15 receptors, for example, is enriched in rafts. This enrichment functionally ensures cytokine selectivity and specificity. Rafts thus assist in the

Figure 1 Comparative kinetics of expression of the membrane markers of activation, CD69, CD25, CD71, and human leukocyte antigen (HLA)-DR in activated healthy human adult T cells.

recruitment of CD25 to the vicinity of the signaling β chain, and promote formation of the (α, β, γ) high affinity IL-2 receptor complex. Activated T cells express the transferrin receptor, CD71, which is critical for the transport of iron from the extracellular environment into the cell during traversal of the DNA synthesis (S) phase. The expression of these and other membrane activation markers, including the exopeptidase CD26 (dipeptidyl peptidase IV) and CD137, the T cell co-stimulatory molecule (4-1BB) antigen, is transient, and exhibits finely controlled kinetics.

Traversal of the Cell Cycle

Successful traversal of the cell cycle depends on finely regulated biochemical pathways. At each critical juncture that signifies passage from one stage to the next, gatekeeper proteins allow or disallow the activated cell to progress. These molecular regulators are proteins, the cyclins, which associate with their respective kinase enzymes. Cyclin/cyclin-dependent kinase cdk phosphorylate key proteins that directly or indirectly modulate gene transcription and allow the activated T cell to move forward in the cycle. Cyclin D consists of a family whose members contribute to the regulation of G1/S transition. In T cells, cyclin D3 associates with either cdk4 or cdk6 late in Gap1 (G1). Cyclin D3-cdk4/6 kinase phosphorylates the retinoblastoma protein (Rb), which then releases the transcription factor E2F required for entry into the S phase and for DNA replication. For instance, at 10^{-9} M, *Panax ginseng* (Ginsenoside [20R]-Rg[3]Rc) blunts protein tyrosine kinase activity by 50%, impairs the phosphorylation of the retinoblastoma protein (Rb), and the expression of cyclin D3 (Figure 2), and leads to a threefold decrease in IL-2 production in response to CD3/CD28 stimulation. Expression of cyclin D3, and of the proliferating cell nuclear antigen (PCNA), and the phosphorylation of Rb are blunted in T cells by 0.1% ethanol, but enhanced by 12 ng ml $^{-1}$ prolactin.

Figure 2 Modulation of cell cycle traversal by ginseng. Normal human T cells were stimulated *in vitro* with immobilized antiCD3/antiCD28 antibody, or the T-cell mitogen phytohemagglutinin, in the presence or the absence of 10^{-9} M ginsenoside Rc (Sigma) for 24 h. Cell extracts were obtained and used for assessment of cyclin D3 (panel A) or retinoblastoma (Rb) protein phosphorylation (panel B) by Western blotting with commercial monoclonal antibodies (Sta Cruz Biochemicals) to measure traversal of G $_1$. Note: Rb phosphorylation is measured as the ratio between the ratio of the upper, ppRb, and the lower pRb bands. TcR, T-cell receptor; PHA, phytohemagglutinin.

At 10^{-8} – 10^{-7} M, the plasma levels of individuals taking ginseng herbal tea, ginseng significantly ($p < 0.05$) stimulates the expression of CD69, and induces a 60% increase in calcium/calmodulin-dependent kinase (CaM kinase) activity. Ion channels are indeed critical in the control of the membrane potential and calcium signaling, and modulate signal transduction pathways following stimulation.

The process and dynamics of cell cycle traversal is monitored by propidium iodide/bromodeoxy uridine (PI/BrdU) immunofluorescent flow cytometry analysis to obtain a timeline sequence monitoring of cells as they traverse G1, S, G2, and mitosis (M). At 10^{-6} M, ginseng has no effect on CD69 expression (4.04 ± 1.34 -fold increase versus 4.30 ± 1.70 -fold increase), on traversal of the cell cycle by PI/BrdU analysis (Figure 3), or on IL-2 production. By contrast, 10^{-6} M mercuric chloride (HgCl $_2$) blunts cell cycle traversal by accumulating activating T cell subpopulations in late S (% cells in S at 48 h, 76.0 ± 13.2 with control versus 91.0 ± 5.0 with HgCl $_2$, $p < 0.07$),

Figure 3 Modulation of cell cycle traversal by ginseng. Normal human T cells were stimulated in the presence or absence of 10^{-6} M ginseng, and the cultures were stained sequentially with propidium iodide (nuclear stain) and bromodeoxyuridine (DNA stain), followed by dual fluorescence flow cytometric analysis. Panel A shows the raw representation of the data from a representative culture, with highlighted the five regions (R1, R2, R3, R4, and R5) that constitute the population of cells traversing the phases of the cell cycle (G_1 , S, G_2 , and M). Panel B shows summary data of the effect of ginseng on cell cycle traversal as monitored by dual fluorescence propidium iodide/bromodeoxy uridine (PI/BrdU). Open bars, control unstimulated; closed bars, control stimulated; hatched bars, stimulated in the presence of 10^{-6} M ginsenoside.

which corresponds to a 50% drop in cell number traversing G_2 and M. However, 0.2% ethanol produces an accumulation of cells in late G_1 (2.5-fold increase, compared to control).

T-Cell Memory – Cytokine Patterns

Monoclonal antibodies against CD45RA can serve to purify naïve T cells from memory T cells ($93.94 \pm 5.51\%$ pure). Dual fluorescence flow cytometry is then used to monitor the maturation of T cells, i.e., the change in proportion from the naïve (CD45RA⁺) to the memory phenotype (CD45RO⁺) following CD3/CD28 stimulation. Kolmogorov-Smirnov analysis quantifies phenotypic T cell maturation. This approach has demonstrated that β -amyloid significantly ($p < 0.05$) blunts the ability of T cells to mature phenotypically.

Cytokines regulate immunity. One aspect of functional maturity of T cells, the variety of cytokines, depends on the initial antigen, and upon the physiological milieu (e.g., modulatory hormones and neuropeptides consequential to the stress response status of the organism). T helper (TH)1 and TH2 patterns of cytokine production are intertwined in terms of both their regulation and their relevance for the overall modulation of immune surveillance in health and disease.

Normal aging and aging-related dementia (e.g., dementia of the Alzheimer's type, DAT) are associated

with significant changes in TH1 and TH2 cytokine production by circulating T cells. Intracellular cytokine staining, following stimulation of T cells in the presence of an inhibitor of protein transport thus retaining the cytokines inside the cell, and double-label immunofluorescence flow cytometry, reveals that normal subjects of 55–70 years of age have trace levels of cytoplasmic IL-10, interferon (IFN) γ , or IL-12 in T cells. Cohorts with DAT show significantly ($p < 0.05$) elevated levels of cytoplasmic IL-10 (2.67 ± 1.15 ng ml⁻¹), IFN γ (3.25 ± 2.25 ng ml⁻¹), and IL-12 (1.78 ± 19.00 ng ml⁻¹) in T cells. In older (>70 years of age) patients with DAT, these levels drop to 1.99 ± 0.61 ng ml⁻¹, $p < 0.06$; 1.25 ± 0.05 ng ml⁻¹, $p < 0.09$; 1.04 ± 0.29 ng ml⁻¹, $p < 0.01$ for cytoplasmic IL10, IFN γ , and IL-12 in T cells, respectively. In addition, the process of immunological aging is evidently distinct in patients with DAT compared to normal subjects, and cytoplasmic levels of IL-10, IFN γ , and IL-12 in T cells rise to levels similar to their age-cohorts diagnosed with DAT in older normal subjects to 1.99 ± 0.70 ng ml⁻¹, 2.75 ± 1.26 ng ml⁻¹, and 1.33 ± 2.07 ng ml⁻¹, respectively.

These changes can be attributed to a plethora of immunophysiological mechanisms within the context of stress and neuroendocrine immunity. The hypothesis has been put forward that age-associated alterations in immunity are associated with the reduction in

hypothalamic dopaminergic tone with aging, related alterations in pituitary hormone, such as the anterior pituitary hormone, prolactin, and interference with the regulation of immunity. For example, 10–15 ng ml⁻¹ prolactin increased IL-2 production by stimulated T cells *in vitro* close to twofold (8.15 ± 2.15 ng ml⁻¹ versus 4.17 ± 1.22 ng ml⁻¹, respectively, $p < 0.09$). The prolactin effect is specific to Th1 cytokines, and is not obtained with the production of the Th2 cytokine, IL-4.

A third pattern of cytokines refers to the effect of certain growth factors (e.g., granulocyte macrophage colony stimulating factor; GM-CSF) in modulating the increase the production of bone marrow-derived antigen-presenting dendritic cells, and the production of IL-23 by these cells. IL-23 belongs to the IL-12 cytokine family, which shares p40, and binds to the IL12 β 1/IL-23R receptor complex to play a critical role in end-stage inflammation via signaling of the Janus tyrosine kinases (JAK) and signal transducers and activators of transcription (STAT) (JAK/STAT) pathway. Administration of IL-11 downregulates IL-12. IL-23 augments production of IL-17 by T cells, which becomes the significant cytokine in the involvement of T cells in inflammation. IL-17 leads to decreased neutrophilia in animal models, and *in vitro* administration of IL-17 synergizes the effects of tumor necrosis factor (TNF)- α for GM-CSF induction, for increased intercellular adhesion molecule (ICAM)-1 (CD54) expression by CD34+ progenitors, for increased neutrophil maturation, and for increased proinflammatory IL-6 and prostaglandin (PG)E2 and granulocyte-colony stimulating factor (G-CSF) growth factor production by keratinocytes and endothelial cells. IL-17 also favors increased secretion of the migration-inducing cytokine, IL-8. In human U937 cells, and probably in all lymphoid and myeloid cells, the JAK/STAT signaling pathway is responsible for transducing signals from the IL-17 receptor. Human vascular embryonic cells (HUVEC) express a homolog of IL-17R, as do ductal epithelial cells of human salivary glands, suggesting a significant role for IL-17 in immunity in the oral mucosa. In fact, in inflamed gingival tissue, IL-17 is the predominant cytokine in tissue proximal to 4–5 mm diseased periodontal pockets. IL-17 plays a critical role in immunity and mucosal inflammation, by modulating the effects of GM-CSF and other growth factors.

Migration

Cell migration is critical to immune surveillance. The migration of T cells is brought about by the concerted

action of specialized factors and receptors, and is regulated by chemokines. Chemokines belong to three groups: C-X-C, C-C, and C depending on the number and position of cysteine. The first group (C-X-C) contains IL-8, growth-regulated oncogene (GRO) α , and GRO β and other chemokines with chemoattractant properties mainly, but not exclusively, towards neutrophils. The second (C-C) and third (C) groups comprise substances like monocyte chemoattractant protein (MCP)1, MCP2, MCP3, and macrophage inflammatory protein (MIP)1 α and MIP1 β , which mainly work on macrophages, lymphocytes, and eosinophils.

Recruitment of immune cells generally occurs by upregulating cell-surface adhesion molecule expression, such as endothelial leukocyte adhesion molecule (ELAM)-1 and increased ICAM-1, thereby enhancing cell adherence to the endothelial surface, and facilitating cell diapedesis through endothelial vessel walls. IL-8 mediates the recruitment and activation of immune cells in inflamed tissue, and increases endothelial permeability *in vitro*.

Plasma levels of IL-8 are raised in subjects with chronic alcoholism without liver disease and even more elevated in subjects with alcoholic hepatitis, who also show a rise in C-X-C chemokines. Alcohol abuse is a typical physiological stress that alters the distribution of monocytes and macrophages, and certain T-cell subsets, including a sharp decline in circulating CD4+CD62L+.

Regulation

Healthy human adult peripheral blood T cells express either CD4 or CD8. CD4 allows T cells to adhere by means of TcR to antigen-presenting cells (APC) that expose antigen in association with MHC-class 2. CD8 favors binding of the T cells to APC that present antigen via MHC-class 1. Most CD4+CD3+ cells act as TH cells, but a few CD4+ T cells are endowed with cytotoxic activity. CD8+ T cells are generally cytotoxic T lymphocytes, but they produce cytokines and growth factors that contribute to T cell-mediated immune regulation.

Membrane and Molecular Level

CD4 and CD8 are complexed lck, are members of the immunoglobulin gene superfamily, but are significantly divergent in their structure: CD4 is a monomer, while CD8 consists of two chains and occurs as a homodimer (α/α) or heterodimer (α/β). lck interacts with the CD4's 20 cytoplasmic relatively acidic residues (408–421), and with CD8 α 's 10 cytoplasmic residues (194–203) via ionic forces and by cysteine

residues. The CD8 β chain does not bind to lck. T cell stimulation leads to internalization of CD4:lck and its dissociation. The homodimeric form of CD8:lck may be internalized, but does not dissociate. The heterodimeric form of CD8:lck is not internalized, and does not dissociate. That is to say, active lck kinase is released in the cytoplasmic environment only following CD4+ cell activation.

A related src family member, fyn, associates primarily, but not exclusively with CD3, and other peptides generally implicated in the regulation of cell proliferation. The carboxyl domain of src family members exhibits a high degree of homology and contains the catalytic site. The N-terminal is unique to each peptide. The catalytic domain exhibits an adenosine triphosphate (ATP)-binding site at lysine 273, a site for autophosphorylation at tyrosine 394, and a site for tyrosine dephosphorylation mediated by CD45, or other phosphatases.

Related molecular events involved in the regulation of T cell stimulation include Akt (phosphoinositide 3-kinase, protein kinase B, PKB), the tumor suppressor, PTEN (phosphatase and tensin homolog deleted on chromosome 10, which removes phosphates primarily from lipids), Ras, mitogen-activated protein kinase (MAPK)/extracellular signal-regulated kinase (MEK), the dual threonine and tyrosine recognition kinase that phosphorylates and activates MAPK, and the novel tyrosine kinase inhibitor peptide, Tkip, a mimetic of SOCS-1 that binds to the autophosphorylation site of JAK2 and inhibits phosphorylation of STAT1 α . Tkip could serve as a potentially important therapeutic target for both constitutive and IL-6-induced STAT3 activation.

Suppressors of cytokine signaling (SOCS) constitute a family of seven known cytoplasmic proteins that regulate the feedback attenuation of cytokine-mediated signal transduction. IL-2 stimulation of T cells induces signaling via JAK/STAT, and SOCS-3 inhibits the JAK/STAT cytokine signaling cascade by directly binding to it, and by preventing access to the signaling complex. IL-2 enhances SOCS-3 messenger ribonucleic acid (mRNA) and protein synthesis, and its phosphorylation on tyrosine residues 204 and 221. SOCS-3 blocks the Ras/MEK activation pathway for c-fos and c-jun. Phosphorylation of SOCS-3 destabilizes its bond to proteasomes via elgulin B and C, and leads to proteasomal destruction. In the 3T3 fibroblast model, activation of SOCS-1 and SOCS-3 inhibits focal adhesion kinase (FAK) activity *in vitro* and tyrosine phosphorylation of FAK. Activation of SOCS promotes polyubiquitination and degradation of FAK in a SOCS box-dependent manner. Together, these events lead to inhibited FAK-dependent signaling events, including cell motility on fibronectin.

Phosphorylation of FAK is an essential regulatory step in T-cell migration.

Another important pathway related to SOCS is the P3 member of the first forkhead-box (FOX) transcription factor (FoxP3). FoxP3 functions as a transcriptional repressor, targeting composite NFAT/AP-1 sites in cytokine gene promoters. The region responsible for NFAT inhibition has now been mapped to the N-terminus of FoxP3. Introduction of FoxP3 into conventional mouse T cells converts these cells to the regulatory T cell (Treg) phenotype (CD4+CD25+).

Cellular Level

Treg are defined phenotypically as CD4+CD25+ T cells. They constitute 7–10% of CD4+ T cells in peripheral blood from healthy donors, and can rise to up to 20% in patients with lymphoma. Depletion of CD4+CD25+ cells significantly ($p < 0.05$) enhances the proliferative response of the remaining CD4+CD25– population, but addition of sorted CD4+CD25+ cells to the CD4+CD25– T cell population blunts proliferative activity. Sorted CD4+CD25+ T cells are susceptible to apoptotic cell death, associated with low Bcl-2 expression, and prevented by IL-2 salvage.

Neuropilin-1 (Nrp1) is a plasma transmembrane receptor (120 kD) involved in axon guidance, angiogenesis, and the activation of T cells. It is a ligand to the class 3 semaphorin subfamily and the heparin-binding forms of vascular endothelial growth factor and placenta growth factor. It acts as another specific surface marker for CD4+CD25+ Treg cells. Nrp1 mediates contacts between the dendritic cells and T cells via homotypic interactions and is essential for the initiation of the primary immune response. It is constitutively expressed on the surface of CD4+CD25+ Treg cells independently of their activation status. Nrp1 is downregulated in naïve CD4+CD25– T cells following TcR stimulation.

Functionally, Treg are endowed with suppressing T-cell activation. Expression of FoxP3, the transcription factor for the scurf protein product, is a master regulatory gene for the development and function of CD4+CD25+ subset. When transduced into T cells, FoxP3 recapitulates the hyporesponsiveness of naïve T cells, including impaired proliferation and production of cytokines including IL-2 and IL-10 upon TcR stimulation. FoxP3 is less efficient in reprogramming memory T cell subset into Treg cells, and is a reliable marker for functional Treg. Expression on the plasma membrane the glucocorticoid-induced TNF receptor (GITR) by Treg cells strongly suggests an important role for SOCS in neuroendocrine-immune regulation.

Different subsets of Treg cells have been identified. Naïve peripheral CD4⁺CD25[−] T cells can be induced *in vitro* into CD25⁺ anergic/suppressor cells through co-stimulation TcR and TGF- β , which induces Foxp3 gene expression. These TcR-challenged CD4⁺CD25[−] naïve can transit toward a regulatory T cell with Treg phenotype and potent immunosuppressive function. Treg are also divided into subsets according to cell-surface expression of CD62L. The suppressive function of the CD62L⁺ subset is far more potent on a per cell basis, can be expanded far more easily in culture, and is more responsive to chemokine-driven migration, compared to the CD62L[−] Treg population. Treg cells may be differentiated based on their expression of chemokine receptors, which may contribute to determine their migration properties: e.g., the traffic to and retention in bone marrow of certain Treg cells through CXCR4/CXCL12 signals.

Clinical Implications

Chemokine receptors serve as co-receptors for HIV-1 infection by binding to certain viral envelope proteins. For example, CXCR4 favors X4 HIV-1 strain tropism, and CCR5 favors tropism of R5 strain. Treg from healthy donors that express the HIV-co-receptor CCR5 are highly susceptible to HIV infection and replication. It is not surprising, therefore, that FoxP3-transduced T cells are markedly more susceptible to HIV infection, and that HIV-positive individuals with a low percentage of CD4⁺ and higher levels of activated T cells have greatly reduced levels of FoxP3⁺CD4⁺CD25⁺ T cells.

CD4⁺CD25⁺ T cells expand significantly in peripheral blood of HIV-seropositive patients receiving highly active antiretroviral therapy (HAART), and exhibit phenotypic (e.g., CD25), molecular (e.g., FoxP3), and functional characteristics (e.g., impaired proliferative and IL-2 production responses) of Treg cells. HIV-seropositive patients under HAART treatment supplemented with intermittent IL-2 show an increase of up to 79% (median, 61%) in CD4⁺CD25⁺CD69[−] cells, with a sharp increase in the proportion of cells expressing the CD45R0 memory phenotype, and Ki67 (proliferating cell antigen) expression.

Treg cells suppress Th1 cytokine responses, and ensure polarization of the Th2 pattern of cytokines during infection, such as schistosomiasis. A rat population of constitutive CD4⁺CD25⁺ T cells has been described that corresponds to Treg cells described in mice and humans, indicating that Treg phenomena are widespread among mammals.

Treg and T cells in general are critical to the regulation of immunity. We recall that T cells generally

express either one of two major subtypes of the TcR. Most T cells in the peripheral blood and in lymphoid organs express the heterodimeric α/β chains TcR. The majority of T cells that express the TcR composed of γ/δ proteins are enriched in epithelial tissues. This distinction is evident to a lesser degree in humans, compared to other mammals (e.g., murine model). Human peripheral blood contains less than 5% of T cells that bear the γ/δ TcR subtype, and in the oro-pharyngo-gastrointestinal mucosa, γ/δ T cells predominate. T cells that express the α/β TcR contribute to the immune surveillance of mucosal tissues. For example, the demonstration that T-cell clones derived from peripheral lymph nodes, and expressing α/β TcR, preferentially home to gingival tissue following infection with the dental plaque micro-organism, *Actinobacillus actinomycetemcomitans*. This migration is blocked by anti-very late antigen (VLA)-4 antibodies. Constitutive Treg cells emerge in the peripheral blood from the thymus, and play a critical role in the control of intestinal inflammation. Lymph node-derived Treg cells can effectively counter established, severe, and progressive colitis. Syngeneic Treg cells obtained from spleens and administered to mice with colitis contribute to the resolution of the *lamina propria* inflammation, and to the reappearance of normal intestinal architecture. Treg cells proliferate in the mesenteric lymph nodes and the inflamed colon of mice under treatment. Another plaque-related organism, *Fusobacterium nucleatum*, induces a threefold increase in CD69 expression by CD4⁺ T cells, and hence in the generation of inducible Treg, compared to a 4.15-fold activation in mitogen-stimulated control cultures. HgCl₂ at micromolar concentrations suppresses the *F. nucleatum*-mediated stimulation of CD69-expressing Treg by over 90%, and significantly ($p < 0.05$) blunts the production of IL-2. At supramicromolar concentrations (e.g., 10^{-5} M), HgCl₂ significantly ($p < 0.05$) increases the expression of CD25 by T cells by almost threefold. Taken together, these observations indicate that Treg from the peripheral and lymphoid system play an important role in the immune surveillance of inflammatory processes of mucosal immunity.

Conclusion

This article has discussed novel mechanisms of the regulation of T cell-mediated immunity. Future research in genomic, proteomic, interactomic, and molecular cartography in general will elucidate the fundamental pathways in immunity and autoimmunity, and reveal new and improved modes of therapeutic intervention for immune-related diseases.

Introduction

Relationship between Terrorism and Other Traumatic Experiences

Differentiating between Acute Mental Health Symptoms That Will Probably Abate and Those That Will Develop into Long-Term or Pathological Mental Health Consequences

Risk Factors for Chronic Posttraumatic Symptoms

The Role of Biological Studies in Helping to Identify Pathological Responses

Introduction

Because the broad goals of terrorism are ultimately psychological, it is imperative to understand the magnitude and scope of the psychological casualties in the wake of terrorism and their biological correlates so as to identify the appropriate means of immunizing people to these effects. Although the majority of people exposed to terrorism experience acute distress, the most important observation to emerge from longitudinal studies of people exposed to terrorism is that these symptoms are transient for the great majority. It therefore becomes important from a public health perspective to be able to predict those at greatest risk for long-term problems. Those at risk for long-term symptoms appear to have a more intense reaction at the time of the trauma (e.g., peritraumatic dissociation, panic, or related emotional distress), associated with a more negative appraisal of danger. It is not clear whether and to what extent pretraumatic risk factors (e.g., prior adversity, family history of psychopathology, cognitive risk factors, or preexisting personality traits) influence the intensity of the peritraumatic response to trauma, but presumably these risk factors are more relevant in situations in which exposure is less severe. Posttraumatic risk factors, such as lack of social support, also seem to

be important predictors of psychopathology, but the extent to which these reflect pre- or even peritraumatic risk factors is currently unknown.

In considering the strength of the information available regarding the psychological consequences of terrorism and their biological correlates, it is important to point to gaps in our knowledge with respect to these issues that currently preclude a thorough understanding of the psychological and biological consequences of terrorism. The first concerns whether psychological outcomes related to terrorism are comparable with those observed in the case of other traumatic events such as combat, interpersonal violence, and natural disasters, whose immediate and long-term consequences have been well established. The second concerns whether the immediate effects of terrorism are pathological, that is, requiring mental health intervention. In the absence of empirical data regarding these gaps in knowledge, governmental and privately sponsored interventions following terrorist attacks are modeled after those developed for responding to natural disasters. Thus, it is important to supply the missing information so that responses to terrorism can be tailored to the specific needs of survivors.

Relationship between Terrorism and Other Traumatic Experiences

Terrorism is a prototypic traumatic event (i.e., it meets the objective and subjective criteria as defined according to the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edn., DSM-IV) for those who directly experience a threat to their life or physical integrity or who experience loss, most notably, the sudden loss of a loved one. However, terrorism is not only about life threat to single individuals, or even a small group of people; it is designed to instill fear in society at large. Thus, in addition to those who experience the effects of terrorism firsthand, there are collateral effects. People who were not in proximity to the target where the terrorist event occurred and people who were not directly affected by the loss of

someone important to them can also be affected in terms of mental health outcomes, particularly because such events often receive repeated coverage on television and other media outlets. It is not known whether mental health consequences in people indirectly exposed to terrorism are qualitatively or quantitatively different from those who have been directly exposed. The additive effect of anticipatory anxiety is also not known, yet the real threat of imminent attack may be related to how quickly those exposed to terrorism can recover from its effects.

In applying knowledge from what has already been learned about the effects of other traumatic stressors, it is clear that a key variable in considering pathological outcomes is the passage of time. Although there are certainly immediate symptoms following any traumatic event, there is debate about whether and how to intervene in the acute aftermath of any trauma because, in most cases, such symptoms abate within weeks and months, and the consequences of interfering with the natural healing processes are unknown. One difference between terrorism and other traumatic events is that a single act of terrorism may represent the beginning or continuation of a situation or threat. In the context of an ongoing terrorist threat, identifying a persistent disorder may be more accurately defined only after the immediate threat of terrorism is substantially reduced in reality. This caveat does not suggest that people do not have mental health needs that should be met within this time frame; rather, it acknowledges that pathological responses that are defined by persistence and chronicity need to be considered in the context of actual ongoing threat.

Differentiating between Acute Mental Health Symptoms That Will Probably Abate and Those That Will Develop into Long-Term or Pathological Mental Health Consequences

The high rate of spontaneous recovery in the aftermath of terrorism raises an important question with respect to how initial symptoms should be understood and treated. If the initial symptoms are understood as transient reflections of distress, it is not clear that such symptoms require mental health intervention. Alternatively, it can be argued that treating early symptoms, even in those who will experience spontaneous recovery, might help prevent long-term responses in the 7–12% who generally remain symptomatic or deteriorate as the broad population begins to improve. Clarifying the causes of high levels of immediate and long-term symptoms

will no doubt lead to ideas about potential preventative treatments because it is now clear that the intensity of the exposure to trauma does not sufficiently predict who will develop or sustain symptoms.

In the absence of a linear relationship between acute stress reactions and longer-term adjustment, there are two theoretical models for pathological responses in the aftermath of a trauma. The first defines a pathological response to trauma by the persistence of the same symptoms that within a specified period of time immediately following the event would otherwise be considered normal. The second defines posttraumatic pathology by the presence of a fundamentally different initial response to stress, resulting in persistent symptoms of hyperarousal, recollection of intrusive events, and avoidance of reminders. Both models are consistent with the idea that posttraumatic mental health consequences are based on a failure to recover from the universal distress in the immediate aftermath of trauma. In the first case, the persistence of symptoms probably results from post-exposure factors that prevent recovery, such as lack of social support or other coping resources. In contrast, the second model implies that the initial symptoms are fundamentally different at the outset and probably result from pre- or peritraumatic factors.

Supporting the idea that persistent responses are simply continuations of initial reactions are the findings that people who show high-magnitude post-traumatic stress disorder (PTSD) symptoms (i.e., intrusive, avoidance, and hyperarousal) in the first few days and from 1 to 2 weeks after the event are those at greatest risk for subsequent symptom severity. However, many researchers performing longitudinal studies of acute trauma survivors have not been able to identify specific symptoms that can convincingly predict pathological mental health outcomes. More promising clinical predictors appear to be the presence of a panic attack and/or intense dissociation during or immediately after a trauma, which suggests additional or fundamentally different immediate responses. Both panic attacks and dissociative responses reflect catastrophic or negative interpretations of the event. Such interpretations may further perpetuate arousal associated with stress responses and reduce the body's ability to achieve homeostasis following the trauma. The presence of catastrophic attributions (e.g., that posttraumatic symptoms signify a major problem and will not ultimately resolve) provides a way of drawing a distinction between being terrorized and being terrified. People exposed to a traumatic event are not traumatized unless they are deeply distraught at the time of the event and then make

catastrophic interpretations that may result in fundamentally different biological stress responses.

Indeed, although trauma exposure certainly results in the release of stress hormones such as catecholamines and cortisol, it has been noted that dissociation and panic attacks are specifically associated with increased catecholamine levels. It may be that a peritraumatic panic attack or other intense distress during and immediately after the traumatic event leads to higher levels of stress hormones that might, in turn, strengthen traumatic memories and increase the probability of intrusive recollections. On the other hand, extreme reactions of panic and dissociation may be facilitated by relatively lower levels of stress hormones, such as cortisol, that play an important role in containing the catecholamine response to stress.

Risk Factors for Chronic Posttraumatic Symptoms

The finding that only a proportion of those exposed to trauma develop short- and long-term symptoms justifies an exploration of both the factors that increase the risk for and the factors that might serve to protect individuals from developing such symptoms following trauma exposure. Although there is not much known about the long-term consequences of terrorism specifically, there is information about factors that contribute to the development of chronic PTSD following exposure to other types of traumatic events. Putative risk factors for PTSD can describe the characteristics of the event or the response to the event or the characteristics of the people who experience those events. Indeed, a wide variety of risk factors, ranging from situational or environmental factors to familial or even genetic risk factors, for PTSD have now been identified. The identification of specific patterns of risk factors is relevant to an understanding of different types of acute reactions and for providing prophylaxis.

It appears on the basis of retrospective studies that those at greatest risk for developing chronic symptoms following a traumatic event are people with prior exposure to trauma, specific cognitive factors, and certain preexisting personality traits, such as proneness to experiencing negative emotions and having poor social supports. However, increasingly, family and genetic studies are pointing toward the role of genetic contributions to posttraumatic stress reactions. The adult children of Holocaust survivors with PTSD show a greater prevalence of PTSD to their own traumatic events than the adult children of Holocaust survivors without PTSD. It is difficult

to know the extent to which increased vulnerability to PTSD in family members of trauma survivors with PTSD can be attributed to being raised by a parent with this disorder, to exposure of the fetus to the mother's stress hormones during pregnancy, or to genetic factors. Evidence that family resemblance with respect to PTSD may be at least partly explained by genes comes from twin studies in which concordance for PTSD was examined in monozygotic and dizygotic twins. However, identifying those at risk will depend on identifying how these genetic factors interact with patterns or risk factors such as childhood trauma, low educational attainment, personal or family history of anxiety or mood disorders, history of heavy alcohol use in the months prior to the incident, poor social supports in the posttraumatic period, and greater levels of exposure during the incident together with symptoms in the peritraumatic period.

The Role of Biological Studies in Helping to Identify Pathological Responses

There appears to be a distinct set of biological alterations in trauma survivors who develop chronic posttraumatic symptoms. Some of these reflect changes in stress-responsive systems that are qualitatively different than those predicted on the basis of the stress literature. Furthermore, the alterations in individuals with PTSD have been found to be distinct from those of similarly exposed individuals without PTSD and also different from those found in other psychiatric disorders, such as mood and other anxiety disorders. Together, these findings suggest that the biology of PTSD is not simply a reflection of a normative stress response but, rather, a pathological one.

For example, in contrast to the normal fear response, which is characterized by a series of biological reactions that help the body cope with, and gradually recover from, stress (e.g., high cortisol levels), some recent prospective biological studies have demonstrated that individuals who develop PTSD symptoms appear to have attenuated cortisol increases in the acute aftermath of a trauma compared to those who do not develop this disorder. Moreover, people who develop PTSD show higher heart rates in the emergency room and at 1 week posttrauma compared to those who ultimately recover, suggesting a greater degree of sympathetic nervous system activation. Thus, it may be that long-term symptoms following trauma are facilitated by a failure to contain the normal stress response at the time of the trauma, resulting in a cascade of biological alterations that lead to intrusive, avoidance, and hyperarousal symptoms.

This difficulty may occur because of pretraumatic biological risk factors.

Basic science research on both memory consolidation and fear conditioning have demonstrated that heightened adrenergic activation can promote the consolidation and retrieval of fear-provoking memories. Thus, extreme sympathetic arousal at the time of a traumatic event may result in the release of stress-related neurochemicals (including norepinephrine and epinephrine), mediating an overconsolidation of trauma memories. The enhanced elevation of catecholamines in the immediate aftermath of a traumatic event may increase the probability of intrusive recollections in the first few days and weeks posttrauma.

One of the major gaps in our knowledge concerns the interplay of biological responses at the time of a traumatic event and cognitive factors. Indeed, it is easy to see how an increased catecholaminergic response to trauma could be the proximal cause of intense panic. Furthermore, it seems plausible that people who find themselves in a more intense biological state of fear might be likely to appraise a situation as more immediately dangerous. On the other hand, it may be that preexisting cognitive factors mediate the catecholaminergic response to the trauma that leads to the panic. These preexisting cognitive factors, in turn, may or may not be the cause, result, or correlate of a preexisting biological alteration that sets the stage for an extreme response.

Clarifying the causes of high levels of immediate and long-term symptoms will no doubt lead to ideas about potential preventative treatments. For example, to the extent that panic reactions are associated with increased catecholamine responses at the time of trauma, aggressive intervention with adrenergic-blocking agents (such as propranolol) or cortisol or cognitive-behavioral stress management techniques emphasizing relaxation rather than any form of retelling (i.e., reexposure, as in debriefing) may be

the most appropriate immediate interventions for people who panic in the hours immediately following a traumatic experience. For people who are not in a position to receive intervention within several hours or days posttrauma, it will be necessary to determine the impact of posttraumatic risk factors such as lack of social support on the longitudinal course of pathological responses to trauma.

Overview
Physiology of Erection
Erectile Dysfunction
Evaluation and Treatment

Glossary

<i>Erectile dysfunction (ED)</i>	Failure to obtain sufficient erectile rigidity of the penis to allow vaginal penetration, also known as impotence.
<i>Erection</i>	Tumescence or engorgement of the corporal bodies leading to elongation, widening, and rigidity of the penis.
<i>Intrinsic/extrinsic stress</i>	Psychological forces a person experiences. Intrinsic stress, for example, could result from guilt over marital infidelity; extrinsic stress, for example, could result from the death of one's parents.
<i>Libido</i>	The desire to have sex.
<i>Nocturnal erection</i>	Normal physiological erection of the penis that occurs subconsciously during the rapid eye movement sleep cycle and, when present, is thought to exclude organic disease as a cause of erectile dysfunction.

Overview

The inability to obtain sufficient penile rigidity to allow vaginal penetration, regardless of the cause, is termed impotence or is perhaps better described as erectile dysfunction (ED). ED is an exceedingly common problem. In fact, nearly half of all men over the age of 40 suffer from some degree of ED at various times. ED is also strongly associated with advancing age. ED is commonly related to medical conditions as well as psychological disorders, and most physicians agree that in many cases there is significant overlap. Stress in the medical literature has been defined as physical or psychological forces experienced by a person. An example of a physical force leading to ED is severe vascular disease; this leads to failure of the physical erectile mechanism. A typical psychological stress leading to ED is depression, which may not

only be the cause but also the result of ED. The role stress plays in the development of ED is significant and often difficult to define.

Physiology of Erection

Neurological and Psychological Aspects

The events that lead to normal penile erection are complex and involve psychological and physiological mechanisms. Volitional erection usually begins with psychological arousal. This involves all of the senses (sight, touch, smell, taste, and hearing) as well as imagination. The sensory input arrives to special areas of the conscious brain via afferent neural pathways. In the case of positive input, the signals are used to create the sensations and fantasy associated with sexual arousal. This process can be modulated by stress and hormonal imbalance. Next are the descending pathways from the brain, leading to erection centers in the spinal cord. From the spinal cord, the pathway leads to the paired cavernosal nerves running alongside the prostate (neurovascular bundles), which are responsible for the induction of erection. This series of neural connections can collectively be termed the efferent pathway. Stimulation of the genital organs sends signals to the spinal erection center, some of which are transmitted up to the brain and others of which lead to the reflex stimulation of the cavernosal nerves. Thus, three types of penile erection are thought to exist. Psychogenic erection is the result of conscious sensory input and fantasy. Reflexogenic erection occurs by a reflex pathway in the spinal cord initiated by genital stimulation. Finally, nocturnal erections occur by an as yet unknown mechanism.

Mechanical Aspects: Penile Hemodynamics

The physiological mechanics of penile erection are fairly well understood. Essentially, the efferent neural activation leads to a change in the blood flow pattern to the penis whereby more blood is trapped in the paired erectile bodies (corpora cavernosum). Thus, there is greater inflow compared to outflow, and the penis elongates, increases in diameter, and develops sufficient rigidity for vaginal penetration. This requires normally functioning arterial, cavernosal, and venous systems. It is obvious on the basis of our current understanding of sexual function that a complex interaction must occur between the psychological and physical aspects of erection and there are many potential areas in which stress can affect the outcome.

Erectile Dysfunction

For treatment purposes, clinicians commonly classify patients as having either organic or nonorganic causes of ED. This division roughly corresponds to physical and psychological causes, respectively.

Organic and Nonorganic Erectile Dysfunction

Organic causes of ED relate to specific malfunctions in the physiological mechanisms of erection, in other words, any pathological process that affects the afferent input, efferent output, or mechanics of erection. For example, multiple sclerosis can disrupt the afferent and efferent pathways, vascular disease or antihypertensive medications can interfere with the erectile hemodynamics, and diabetes may affect multiple physiological mechanisms.

Nonorganic ED refers to problems that cannot be explained easily by the failure of physiological mechanisms; it is also commonly referred to as psychogenic impotence. This type of ED has defied universally accepted classification; however, it has been subdivided into five major categories: type 1, anxiety, fear of failure (e.g., performance anxiety); type 2, depression; type 3, marital conflict, strained relationship; type 4, ignorance and misinformation, religious scruples (e.g., about normal anatomy or sexual function); and type 5, obsessive-compulsive personality (e.g., anhedonia).

Stress and Erectile Dysfunction

The role stress plays in the causation of ED has been difficult to study and therefore information is lacking. Several commonsense inferences can be made. First, the presence of ED, regardless of the cause, leads to psychological stress such as fear of underlying disease and loss of self-image. Second, intrinsic and extrinsic causes of psychological stress can lead to physiological changes altering the afferent and efferent pathways as well as the mechanical function of erection. For example, anxiety states can be associated with higher circulating levels of catecholamines and these neurotransmitters can affect the hemodynamics of the penis, causing failure of the normal erectile mechanism. This may explain some cases of ED due to performance anxiety. Finally, emotional tone can have a strong influence on how the senses are interpreted, potentially turning positive signals into inhibition of erection; thus, stress can diminish libido profoundly.

Evaluation and Treatment

History and Physical Examination

The evaluation of patients with ED has generally been performed by either urologists or psychiatrists. With changing attitudes toward sexuality and the advancement in the science of ED, many different types of

doctors now possess the appropriate evaluation and management skills. Still, however, sexual dysfunction often remains overlooked in the treatment of many patients. The initial evaluation begins with a thorough history and physical examination. In cases in which psychological factors seem to predominate, the careful elucidation of the history is especially important and often is the only means by which the psychological stress can be discovered. The encounter is best suited to a quiet, comfortable examining room and the history taken with the patient fully clothed, followed by the physical examination. This allows the interaction to occur in a minimally intimidating format. Elements of the history that are relevant include a specific description of the degree of dysfunction, duration, circumstances associated with the onset, coexisting medical problems, loss of libido, past surgeries, injuries, medications, psychiatric problems, and temporal relationship to major life events. On occasion, it is informative to interview the partner separately. The physical examination should focus on signs of systemic disease; thorough neurological evaluation; careful inspection of the genitalia, including rectal examination; and assessment for hormonal and vascular diseases.

Special Testing

On the basis of the initial interview, additional or second-line studies may be needed. These additional tests could include nocturnal penile tumescence (NPT) monitoring, injection cavernosometry and cavernosography, hormonal evaluation, and personality questionnaires.

Nocturnal penile tumescence monitoring The application of NPT monitoring is simple and can usually be performed at home by the patient. Either a one-time-use snap gauge device or an electronic monitor is applied to the penis at bedtime. The presence of normal nocturnal erections is considered proof that the mechanical aspects of penile erection are functioning appropriately. Both devices can measure the presence of an erection and, to some degree, the quality. The more sophisticated electronic monitor provides additional information, such as the number and duration of erections.

Injection cavernosometry and cavernosography Injection cavernosometry and cavernosography are invasive tests in which a vasoactive drug (e.g., prostaglandin) is injected directly into the body of the penis. The drugs work by stimulating the same hemodynamic changes as in normal erection. Before and after injection, pressures within the corporal bodies can be measured to determine an objective degree of tumescence, high-resolution ultrasound can be used to assess vascular changes, and intravenous contrast can be administered for the evaluation of venous leak.

These tests are used to detect arterial (inflow) and venous (outflow) diseases.

Both NPT and injection testing are intended to evaluate the physiological mechanism of erection. The use of these tests is directed not only by the suspected diagnosis but also, and perhaps more important, by potential therapeutic alternatives. Stated differently, extensive physiological testing affects the choice of treatment options infrequently and therefore is indicated only in select cases.

Hormonal evaluation Suspicion of a hormonal imbalance needs to be confirmed by blood tests assessing the function of the pituitary (prolactin), thyroid (thyroid hormones T_3 and T_4 and thyrotropin), and testicle (testosterone). Common abnormalities causing decreased libido include hypogonadism and hypothyroidism. It is important to note that psychological stress can decrease libido without lowering testosterone or thyroid hormone levels. If testosterone is found to be low, then prolactin should be measured; a significant elevation of prolactin can indicate a pituitary problem.

Personality questionnaires Another second line type of testing that is seldom used by urologists and occasionally used by psychiatrists is personality questionnaires. Many have been developed (e.g., the Minnesota Multiphasic Personality Inventory), and they are intended to elicit information similar to a sexual history. The use of this technique may offer advantages in assessing the degree of psychological stress. Many clinicians feel that a detailed personal interview is equally effective, if not more so, and requires less interpretation skills than these instruments. This explains their infrequent use.

Treatment

For the successful management of ED, it is necessary to understand the degree to which both psychological and physiological factors are contributing. For instance, the successful correction of anxiety disorder is helpful, but ignoring concomitant vascular disease will result in treatment failure. Likewise, the placement of a penile prosthesis can restore an adequate erection, but if the patient has a depressed mood he may not be interested in having sex. Treatment is therefore directed toward both the correction of physiological malfunctions and behavioral modification. Furthermore, managing the physiological and psychological factors must be considered in the context of available treatment options. A precise cause can often be determined, particularly when physiological disease predominates, but cannot be precisely corrected given the current limitations in treatment. Thus, in most cases of ED, treatment is directed at the symptoms and not the specific cause.

Physiological treatments There are several approaches to the physiological treatment of ED. These options, from least to most invasive, include an external vacuum erection device (VED); medications in oral pill, intraurethral pellet, and intracavernosal injection; and surgical prosthesis placement. The VED works by creating negative pressure around the penis, thereby causing blood engorgement and erection. It is useful in all types of ED and leaves no permanent changes. Various medications have been used and all affect penile hemodynamics. Oral medications leave no permanent change and effectiveness depends on the cause of ED. Typically, injection therapy is considered most reliable, but it can ultimately lead to corporal fibrosis. Penile prostheses are mechanical devices that are surgically implanted to replace the cavernosal tissue. Implants come in a variety of types, including semirigid and inflatable. In general, treatment is offered from the simplest to the most invasive, depending on the patient's wishes and therapeutic effectiveness.

A major breakthrough in ED medicament treatment was provided by the discovery that phosphodiesterase 5 (PDE5) inhibitors were effective in helping to induce penile erection. PDE5 inhibitors increase the concentration of cyclic guanosine monophosphate in the corpus cavernosum: this results in smooth muscle relaxation (vasodilation) with consequent increased inflow of blood into the corpus cavernosum and penile erection. In 1998, the FDA approved a potent PDE5 inhibitor, sildenafil ("Viagra"), as an oral treatment for ED. Since then several clinical trials, including three independent double blind controlled trials in patients with erectile dysfunction, have demonstrated that sildenafil was significantly more effective than placebo in producing sustained improvements in confidence, self-esteem, and almost normal erectile function. Other effective PDE5 inhibitors, tadalafil ("Cialis") and vardenafil ("Levitra"), are now also available and widely used for the treatment of ED.

Psychological treatment Incorporated into any ED treatment plan must be a provision for the psychological component. This is particularly relevant for ED associated with stress and is probably most useful in patients without significant organic disease. First, any discovered psychological diagnosis, such as depression, should be treated appropriately. Second, sex therapy counseling should be used, not only to uncover functional problems but also to direct intervention and alter negative patterns of behavior. Sex counseling is usually performed by therapists specially trained in sex therapy. The session or sessions will probably require both partners to participate and may involve assignments and exercises to be performed at home. The goals of this intervention are to identify and correct behavioral patterns and to develop coping skills

for sources of internal and external stress. In many cases of stress-associated ED, a combination of both physiological and psychological therapies are used.

Problems Associated with Uncontrolled Anger

Assessment of Anger

Methods of Anger Control

Conclusion

Glossary

Cognitive behavior therapy

A short-term psychotherapy for emotional disorders that aims at symptomatic, affective, and behavioral improvement through the evaluation and modification of an individual's dysfunctional way of processing information.

Idiographic measures

Measures that are not standardized but are devised to assess problems specific to an individual.

Nomothetic scales

Scales validated and standardized in normals and specific comparison groups, yielding norms for different client populations.

Impulse control can relate to several aspects of behavior, for example, anger, substance abuse, repeated self-harm, or suicidal attempts. Anger control is the primary concern of this article.

Problems Associated with Uncontrolled Anger

Anger can be seen as a normal emotional reaction experienced universally by adults and children, as well as by animals. As such, it serves a useful purpose in letting others know that their behavior is aversive so that they can alter their behavior if amicable or respectful relationships are to be maintained or restored. Anger directed at the self allows one to register unpleasant arousal, perhaps at transgressing one's own rules, again allowing for changes to occur. Anger or hostility can be seen as being composed of affective (irritability, full blown anger), physiological (increased arousal), cognitive ("you should not do that," "you are overstepping the mark"), and behavioral (sarcasm, verbal abuse, assault) components. It is when these interacting components reach the point at which anger and hostility are no longer controllable and are expressed in ways that entail negative social and interpersonal consequences that they become a problem. Thus, in the clinic, patients complain of their increased irritability, of anger being provoked by minor triggers, and of their fear of catastrophic consequences. In forensic settings, anger and impulse control are often the main treatment targets.

Anger and hostility have not been widely studied in the clinical literature, relative, say, to depression and anxiety. However, the rising rates of violent crime among adolescents, acts of uncontrolled anger as seen in road rage, violent familial discord, child abuse, and assaults have made uncontrolled anger and hostility a topical subject in the media. Moreover, poorly

managed anger has been linked convincingly with a number of health problems, such as coronary artery disease and essential hypertension. Friedman and Rosenman postulated that type A behavior, characterized by striving for achievement, competitiveness, vigilance, impatience, and easily aroused hostility, predicted coronary heart disease (CHD). The wealth of research that followed has implicated anger and hostility as the component of the type A complex that best predicts CHD and mortality in general.

Several explanations have been put forward to explain the link between hostility/anger and health. The psychophysiological reactivity model proposes that hostile individuals react to stressors with extreme cardiovascular and neuroendocrine responses, which, over time, lead to the development of CHD and CHD symptoms such as myocardial infarction and angina. The psychosocial vulnerability model implicates increased interpersonal stressors and decreased social support, both at work and in daily life. The transactional model integrates the first two models – the hostile individual elicits negative reactions from others, which helps to confirm his or her views of others as antagonistic, increasing hostile tendencies further. Thus, there is a reciprocal relation between the cognitive and behavioral aspects of hostility, leading to increasingly exaggerated cardiovascular and endocrine reactions to intensifying interpersonal stressors. In a study of male patients with postmyocardial infarction and unstable angina, Hall and Davidson found that patients who had higher scores on a measure of hostile style, as rated during a standard interview, perceived the interviewer as more aggressive, although this perception was not corroborated by an independent rater.

Assessment of Anger

The assessment of anger in research studies is usually by standard interview or by nomothetic scales. Some studies have used physiological measures, such as systolic blood pressure in response to potentially anger-arousing stimuli; others have used observers' ratings of facial expressions or behavioral measures, such as hand dynamometer readings.

Interview methods are not validated easily, are time-consuming to administer, and are costly in terms of interviewer training and scoring. Self-rated questionnaires, tested psychometrically for their validity and reliability, have been most widely used. The Cook–Medley hostility scale relates more to cognitive than behavioral aspects of anger; in particular, high scores reflect a negative view of disparagement by others. The Buss–Durkee hostility inventory attempts to measure angry cognitions as well as the verbal and physical expression of anger. Anger, as a trait, can

be assessed by the trait anger scale, which measures cognitive and affective aspects of anger. Novaco developed the anger inventory to measure anger in response to a wide range of potential provocations. Deffenbacher and colleagues have devised a number of idiographic measures to assess anger in day-to-day living; the most intense, ongoing source of anger for the individual; and anger-related physiological arousal. These three idiographic measures are correlated positively with one another and with other indices.

More recently, Snyder and colleagues have developed a scale to measure hostile automatic thoughts (HAT). Automatic thoughts, as described by Beck, are the characteristic self-statements or images that flash into individuals' minds in reaction to external and internal triggers. They are not controlled, occur as reflexes, and are the products of assumptions, attitudes, and beliefs regarding ourselves and the world that derive from our past experiences. The HAT consists of 30 items, rated on five-point likert scales (1, not at all; 5, all the time), reflecting hostile thoughts that involve physical aggression, derogation, and revenge toward other people. It has been shown to be psychometrically valid and reliable.

Self-report measures are easy to administer and score, but they are not immune to faking if respondents desire to present themselves favorably. Hostility is generally considered to be socially undesirable, and low scores on hostility scales may be the result of faking good. This methodological issue may be resolved using a variety of scales that have been shown to be psychometrically sound, as well as using behavioral and observer ratings.

Methods of Anger Control

The majority of anger treatment outcome studies have used a cognitive-behavioral approach, involving methods aimed at reducing the occurrence of anger, regulating levels of arousal when angry, developing new skills in the face of provocation, and preventing conflictual situations from escalating. These treatment approaches have variously been labeled as stress inoculation training, based on Meichenbaum's methods for modifying self-statements in anxious patients; inductive social skills training, based on the principles of cognitive therapy; or cognitive relaxation coping skills. All these approaches have a lot in common, putting more or less emphasis on different aspects of cognitive-behavior therapy (CBT). Treatment can be applied individually or in groups.

Engaging the patient in treatment is of primary importance because patients with more anger are typically suspicious, avoidant, and provoking. Patients need to develop trust in the therapist, learn

to differentiate between different types and levels of affect by self-observation and self-monitoring, recognize the costs of uncontrolled anger, and thus become motivated to change. Following this preparatory phase of treatment, various cognitive and behavioral methods are used. Cognitive restructuring aims to help patients modify their appraisals of threat and provocation, develop appropriate problem-solving thinking, adopt coping self-statements, and modify their basic attitudes regarding themselves and others.

To reduce arousal, methods such as controlled breathing, muscle relaxation, using relaxation imagery, and engaging in alternative tension-reducing activities are taught. Clients need to develop coping skills other than violent expressions of anger. These may include strategic withdrawal, negotiation, appropriate verbal and nonverbal communication, and respectful assertiveness.

In a recent meta-analytic study, Beck and Fernandez analyzed 50 studies incorporating 1640 subjects, published from 1970 to 1995, that used CBT. They reported a grand mean weighted effect size of 0.70, indicating that the average CBT client did better than 76% of untreated subjects in terms of anger reduction. This effect was statistically significant, robust, and relatively homogeneous across studies.

Conclusion

Anger, as other negative impulses, can be viewed as an affective stress reaction with cognitive and behavioral determinants. It can lead, when uncontrolled, to important catastrophic social, interpersonal, and physical health outcomes. Although ignored for a long time compared to other negative emotions such as depression and anxiety, it has been the subject of increasing interest in psychological and psychotherapeutic research.

Incest: Definition and Descriptive Characteristics

Diagnosis

The Psychological Impact of Incest

Treatment of Incest Victims

Glossary

Incest

A type of sexual abuse in which the abuser is a family member.

Nonoffending parent

The nonabusive parent, who typically has custody of the child.

Perpetrator

The family member who abuses the child.

Posttraumatic stress disorder (PTSD)

A stress disorder that includes three categories of psychiatric symptoms in response to a traumatic life event.

Sexual abuse

Sexual exploitation involving physical contact between a child and another person.

Incest: Definition and Descriptive Characteristics

Sexual abuse can be defined as sexual exploitation involving physical contact between a child and another person. Exploitation implies an inequality of power between the child and the abuser on the basis of age, physical size, and/or the nature of the emotional relationship. There can also be noncontact sexual abuse, which includes exposing a child to pornography, taking photographs or videotaping a child for sexual purposes, or sexual exploitation through the Internet.

Incest is a type of sexual abuse in which the abuser is a family member. The abuser may be a parent, step-parent, grandparent, older sibling, or other close relative. Sociological surveys by Finkelhor and others have suggested that 25–30% of all girls and 10–15% of all boys are sexually abused by the age of 18. The proportion of sexual abuse that is incestuous in nature is not absolutely known, but in clinical studies it seems to account for approximately one-half of all reported cases.

Incest is not limited to sexual intercourse. It also includes oral or anal intercourse, fondling of the breasts or genitals, and sexualized, inappropriate kissing. The empirical literature suggests that approximately 50% of incest cases involve oral, anal, or vaginal intercourse while the other half involve genital fondling. Violence is not typically perpetrated against a child victim as part of an act of incest, although threats of violence are common. A child may be coerced to participate in a sexual experience through the promise of rewards or the threat of punishment. In some families, children who are sexually abused may also be physically abused or witness domestic violence.

Children may be victimized by incest at any age. Despite the public misconception that only girls are victimized, boys may also be subjected to an incestuous relationship. The great majority of perpetrators of incest are male, with statistics suggesting that males account for 90% or more of reported cases. The severity of incest can vary from one episode of genital touching to hundreds of episodes of sexual abuse, including intercourse, which may extend over many years. Although incest is commonly reported across all socioeconomic classes, studies by Finkelhor have demonstrated that poor children are more vulnerable to this type of victimization.

Diagnosis

In the nomenclature of the American Psychiatric Association (*Diagnostic and Statistical Manual*, 4th edn.-TR), sexual abuse or incest is not usually considered to be a primary diagnosis (axis I) but is classified

as a psychosocial stressor (axis IV) that may contribute to the primary diagnosis. (However, in situations in which the sexual abuse of the child is the primary focus of clinical attention, it can be coded on axis I.) Children who are victimized by incest do not manifest a unitary syndrome of traits, characteristics, or symptoms. Although, as a group, incest victims display more emotional and behavioral symptoms than normal children, these problems are typically diverse in nature. Moreover, approximately 30% of all incest victims are asymptomatic. Sexual preoccupation or sexualized behaviors are more common in incest victims than nonvictims, but the latter group may exhibit these problems as well. Overall, the general conclusion is that incest cannot be diagnosed based solely on the symptom presentation.

On medical examination, less than 20% of all incest victims display significant clinical findings. Even in cases in which the victim has been vaginally or anally penetrated, significant physical findings may not be present. Accordingly, the absence of significant physical findings does not mean that incest has not occurred.

Determining that incest has occurred is a complex legal and clinical problem. With very young children, they may engage in sexualized behaviors and only disclose alleged abuse after being questioned by the nonoffending parent. Older children may disclose the alleged victimization to a friend, relative, teacher, or other trusted adult. In the great majority of incest cases, the alleged perpetrator initially denies the victimization. In the absence of significant medical findings or a perpetrator confession, it is ultimately very difficult to prove that incest has occurred.

Interviewing the alleged victim is the most frequent method used to determine whether incest has been perpetrated. The nonoffending parent typically provides background data and information about what the child has previously disclosed. If the alleged perpetrator is a parent, he or she may also be interviewed; however, it is recommended that this be done at a separate time from the alleged victim. Most experts recommend that a comprehensive evaluation, including interviews with both parents, be conducted when incest is disclosed in the context of divorce or custody issues.

Over the past 15 years, many concerns have been generated regarding the procedures used to interview alleged sexual abuse and incest victims. Questions have been raised about children's memory and their ability to recall accurately what allegedly occurred. Laboratory research related to this issue has provided mixed results, with some studies suggesting that children do accurately recall the core features of significant events and other studies indicating that children

can produce inaccurate information, particularly in response to repetitive or coercive-like questions. In this regard, criticism sometimes has been directed at child protective service workers, mental health consultants, and other investigative interviewers for allegedly pressuring children to make abuse disclosures or for using inappropriate interviewing techniques (i.e., leading questions). Unfortunately, with the exception of some highly publicized cases, it is impossible to know how often investigations of sexual abuse and incest have been contaminated by improper interview strategies.

In light of the significant issues related to interview methods, some professional guidelines have been promulgated to address this problem. For example, the American Professional Society on the Abuse of Children has developed guidelines for the evaluation of suspected sexual abuse in children, and the American Academy of Child and Adolescent Psychiatry has established practice parameters for the forensic evaluation of children and adolescents who may have been physically or sexually abused. Although it is impossible to know to what degree investigative interviewers are aware of and follow these guidelines, in the past few years there seem to be fewer concerns about inappropriate interviewing procedures.

The Psychological Impact of Incest

As mentioned earlier, children who have been victimized through an incestuous relationship may display a variety of emotional and/or behavioral difficulties subsequent to disclosure. Despite the diversity of the symptom presentation of this population, a number of studies have reported that 20–50% of sexual abuse and incest victims meet full or partial criteria for PTSD. The symptoms of PTSD fall into three categories: re-experiencing symptoms (i.e., intrusive thoughts, nightmares, and flashbacks), avoidance symptoms (i.e., avoid thoughts or feelings about the trauma, emotional detachment, and inability to recall important aspects of the trauma), and symptoms of increased arousal (i.e., sleep disturbance, hypervigilance, and difficulty concentrating). Other psychiatric sequelae of incest may include clinical depression, other anxiety disorders, low self-esteem, sexually reactive behaviors, and, for adolescents, substance abuse problems.

Recent studies have suggested that the frequency and severity of psychiatric symptoms in sexual abuse and incest victims may be mediated by their attributions and perceptions related to the victimization. Thus, victims who feel different from other children, who blame themselves for the abuse, who feel that others do not believe what they say, or have a decreased amount of interpersonal trust are at higher risk for

more serious symptomatology. In particular, children who feel that they are to blame for the victimization are more vulnerable to experiencing depressive disorders.

Legal proceedings may also have an impact on outcome. There is some evidence that when legal proceedings are delayed, emotional/behavioral symptoms in sexual abuse victims tend to increase. Also, when children have to testify in court and are subjected to a very hostile cross-examination or are required to testify multiple times, psychiatric symptomatology appears to worsen.

The psychological impact of being victimized by an incestuous relationship may be moderated by several factors. A number of major studies have demonstrated that emotional support of the victim from the nonoffending parent, which includes not blaming the child for the victimization, has a highly beneficial effect and is correlated with fewer psychiatric symptoms in the victim. Also, as we would anticipate, many nonoffending parents have highly intense emotional reactions to their child's disclosure of incest. These emotional reactions may include anxiety, guilt, anger, and shame. Recent empirical investigations have shown that, when nonoffending parents are able, over time, to resolve their emotional upset related to their child's victimization, this correlates with a reduction in the frequency and severity of the child's emotional and behavioral symptoms.

Treatment of Incest Victims

The treatment of incest may involve a variety of interventions, including individual and/or group therapy for the child victim, supportive therapy with the nonoffending parent, counseling for the perpetrator, and family therapy. Space does not permit a discussion of perpetrator treatment, except to say that most incest perpetrators initially deny victimizing the child and/or minimize its impact and typically require long-term therapy to address their difficulty in taking responsibility for the abuse, cognitive distortions, and issues related to potential relapse.

With the increased attention to and reporting of sexual abuse over the past two decades in the United States, a proliferation of clinical programs has occurred that focus on victim treatment. Unfortunately, the efficacy of the interventions offered in most of these programs has not been investigated. Nonetheless, there is now strong empirical evidence that Trauma-Focused Cognitive Behavioral Therapy (TF-CBT) is an efficacious treatment for sexual abuse and incest victims. Specifically, TF-CBT has been found to be superior to nondirective supportive therapy in reducing PTSD, depressive symptoms, shame, and general behavioral difficulties in the victimized child and

parental distress and depressive symptoms in the non-offending caretaker. This pattern of results has been replicated in a large multisite study of sexual abuse victims, most of whom had also been subjected to other traumatic events.

There are a number of core components of TF-CBT. These include psychoeducation, stress reduction strategies (e.g., relaxation training), creating a trauma narrative, cognitive processing to address inappropriate attributions (i.e., self-blame), and the development of safety and other coping skills.

Work with the nonoffending parent is an essential component of TF-CBT for sexual abuse and incest victims. Critical interventions with the nonoffending parents include addressing their attributions about the sexual abuse, enhancing their support of the victimized child, and behavioral management strategies.

In some treatment programs for incest families, family therapy is the intervention of choice. This is true even though family treatment has not been widely investigated empirically as a potentially effective therapeutic strategy for incestuous families. Family therapy for incest is based on the belief that family dynamics either contribute to the occurrence of the incestuous situation, help maintain the secrecy of the incestuous relationship, or can be changed to prevent future episodes of victimization. The perpetrator of the abuse may be included in family treatment, especially if there is a possibility of family reunification. However, the inclusion of the perpetrator in family sessions would typically occur only after the perpetrator has experienced extensive individual and/or group treatment and has been willing to accept total responsibility for the victimization.

Absolute Income and Health
Relative Income and Health
Income Inequality and Health
Income and Health: The Role of Social Comparisons

Glossary

<i>Absolute income</i>	The measure of the actual income of the individual; linked to the absolute income hypothesis.
<i>Absolute income hypothesis</i>	The idea that health of individuals depends on their own (and only their own) level of income.
<i>Comparative group</i>	The social group to which an individual compares him- or herself.
<i>Income inequality</i>	The measure of the extent of income dispersion in a society or a community; measures such as Gini coefficient are summary measures that quantify the extent of income dispersion in a society.
<i>Membership group</i>	The social group of which an individual feels a part.
<i>Neomaterialist theory</i>	A theory that emphasizes the importance of access to tangible material conditions, both elementary (e.g., food, shelter, and access to services and amenities) and nonelementary (e.g., car and home ownership and access to telephones and the Internet).
<i>Normative group</i>	The social group from which a person takes his or her standards or norms; this could be either the membership or the comparative group.
<i>Psychosocial effects</i>	The direct or indirect effects of stress stemming from either being lower on the socioeconomic hierarchy or living in conditions of relative socioeconomic disadvantage, which facilitates constant social comparisons.
<i>Relative deprivation</i>	The condition in which individuals or groups subjectively perceive themselves to be unfairly disadvantaged compared to others who they perceive as having similar attributes and deserving similar rewards (typically their reference groups or groups to whom they typically compare themselves).
<i>Relative income</i>	The measure of the income of the individual in relation to the incomes of

others in the society or group in which the individual resides. It is linked to the relative income hypothesis.

Relative income hypothesis

The idea that health depends not just on an individual's own level of income but also on the incomes of others in society.

Social comparison

The metric that results from an individual's self-comparison of some other individual or group of individuals on certain dimension, such as income, education, and material possessions.

Differential exposure to stressors is one of the links through which income is associated with health. Income can be conceptualized in absolute or relative terms, with each having distinct mechanisms through which income is hypothesized to influence stressful experiences, thereby affecting health.

Absolute Income and Health

The absolute income hypothesis posits that:

$$h_i = f(y_i), \quad f'_i > 0, \quad f''_i < 0 \quad (1)$$

where h_i is an individual's level of health, and y_i is that individual's own level of income. The relationship between individual income and individual health is concave; that is, every additional dollar is associated with diminishing returns to health. The relationship of individual income to health outcomes is often described as a gradient – at each level of income, individuals experience better health than those immediately below them. On the other hand, to describe the association between income and health as a gradient is possibly misleading because the relationship has been shown to be nonlinear; that is, there are diminishing returns to health improvement with additional rises in income. The concave relationship between income and health has been corroborated in numerous empirical demonstrations, in affluent countries as well as in poor countries. The absolute income hypothesis has been closely associated with the neomaterialist interpretation of the relationship between income and health, which posits that income matters for health because it confers on individuals the ability to purchase goods and services (e.g., health insurance, housing, and nutritious foods) that are necessary for maintaining health, even though the absolute income hypothesis could equally well have a psychosocial effect.

We can also posit a societal or community-level analog of the absolute income hypothesis, such that:

$$h_{ij} = f(Y_j, y_{ij}) \quad (2)$$

where the health of individual i in community j is now hypothesized to be a function of not just his or her own income (y_{ij}) but also of the average income level of the community (Y_j) in which the individual resides. Indeed, a neomaterialist interpretation of the absolute income hypothesis need not be restricted to the availability of income at the individual level; it can also reflect the presence or absence of collective infrastructure at a population or community level. Deprived communities (i.e., communities with high levels of absolute poverty) are less likely to have services and amenities (e.g., health clinics and supermarkets) that are essential for protecting and promoting the health of their residents. Even if an individual resident is not poor, his or her health may be detrimentally affected by living in such a community. A growing number of multilevel studies have now demonstrated that community poverty is linked to higher mortality, higher morbidity, and a more adverse pattern of health behaviors, even after taking into account individual incomes.

Relative Income and Health

In contrast to the absolute income hypothesis, the relative income hypothesis posits that:

$$h_i = f(y_i - y_r) \quad (3)$$

where health of an individual i is a function of the term $(y_i - y_r)$, which denotes the relative gap between an individual's income y_i and the income of some reference population y_r . The reference population could be the income of coworkers, neighbors, or the national population. The concept of relative deprivation was first rigorously formulated by Runciman. According to Runciman, "we can roughly say that A is relatively deprived of X when (i) he does not have X, (ii) he sees some other person or persons, which may include himself at some previous or expected time, as having X (whether or not this is or will be in fact the case), (iii) he wants X, and (iv) he sees it as feasible that he should have X" (Runciman, 1966: 10).

Runciman further conceptualizes the concept of relative deprivation in terms of magnitude, frequency and degree. "The magnitude of the relative deprivation is the extent of the difference between the desired situation and that of the person desiring it (as he sees it). The frequency of a relative deprivation is the proportion of a group who feel it. The degree of a

relative deprivation is the intensity with which it is felt" p.10.

Runciman went on to elaborate three types of reference groups. The first is the membership group, of which an individual feels a part; the second is the normative group, "the group from which a person takes his standards" (Runciman, 1966: 12); and the third is the comparative group, which is the group to which an individual compares him- or herself. Significantly, these different sources of relative comparisons may well coincide, as in Runciman's example of members of the middle class who aspire to be aristocracy and who try to emulate the behavior of the upper class (the normative reference) as well as to attain their status (the comparative reference). Building on these sources of relative comparisons, he further proposed two forms of relative deprivation, depending on the source: egoistic deprivation (relative deprivation of an individual with respect to his or her own group) and fraternalistic deprivation (relative deprivation of an individual's own group compared to other groups in society).

Note that relative deprivation theory, as the phrase suggests, presumes that individuals typically make relative comparisons of themselves to those who are better off than they are and not to those who are worse off. The latter comparison is referred to as relative gratification or relative satisfaction. Indeed, relative deprivation measures happen to be correlated with relative satisfaction.

Although the theory of relative deprivation is quite sophisticated, the empirical identification of reference groups has proved tricky. Empirically, the relative income hypothesis has been operationalized using variations of [equation \(3\)](#), with an important operationalization provided by Yitzhaki, following Runciman's theory. Thus, for a person i with income y_i who is part of a reference group with N people, Yitzhaki's index is given as:

$$RD_i = (1/N) \sum_j (y_j - y_i), \quad \forall y_j > y_i \quad (4)$$

where the amount of relative deprivation (RD) for individual i is the sum of the incomes of j individuals who have incomes higher than that individual. The summation in [equation \(4\)](#), $\sum_j (y_j - y_i)$, is divided by the number of people in the reference group, N , making the measure invariant to size. If income is the object of relative comparison, then we can assess relative income deprivations by groups, based on, for instance, the state of residence, age group, race, educational attainment, gender, or occupation.

The British Whitehall Study of civil servants is frequently cited as evidence showing the health effects of relative deprivation (even though the study did

not include any specific or explicit measures of relative deprivation). In that study, relatively lower-ranked civil servants were shown to have three times the mortality rate as the highest ranked civil servants, despite having access to the same National Health Service. Moreover, none of the subjects in the civil service cohort was deprived in an absolute sense; that is, they all had adequate nutrition, housing, and access to other material amenities. The mortality differential between civil service grades was thus attributed – at least in part – to the adverse psychosocial consequences of relative deprivation. Indeed, systematic tests suggest that people do take into account relative income position when making real-life decisions such as choosing between two earning schemes. For instance, Frank and Sunstein (2001) hypothesized two possible scenarios. In scenario A, the individual earns \$110,000 per year and others earn \$200,000; in scenario B, the individual earns \$100,000 per year (less than in world A), but others earn only \$85,000. Contrary to traditional economic perspective (wherein world A should be preferable because it offers higher absolute consumption), a substantial number of respondents opted for world B.

As we mentioned earlier, the absolute income hypothesis tends to be interpreted in materialist terms, whereas the relative income hypothesis tends to be interpreted in psychosocial terms. This dichotomy is unwarranted. For instance, the absolute income hypothesis is equally compatible with the psychosocial interpretation. That is, if lower income is associated with more stress (e.g., inability to pay the bills and to plan for the future), then an individual could end up with an income–health gradient even if no social comparison is taking place.

Analogously, the relative deprivation hypothesis could also be interpreted both ways (neomaterial as well as psychosocial). That is, an individual's social comparison to a reference group could be stressful (the psychosocial interpretation) or he or she may be unable to function in society because of limited access to material commodities (e.g., car ownership, Internet access, or air conditioning). For example, rising community living standards are often associated with an enlargement of the range of consumer goods that are necessary for an individual to function as a member of that community. Many consumer goods, such as central heating/air conditioning, telephone, and access to the Internet, have followed this trajectory, starting out as luxury goods and eventually ending up as necessities. Even if an individual is not deprived in any absolute sense (i.e., has adequate nutrition and housing), relative deprivation (compared to the standard basket of commodities that everyone else has access to) could adversely affect his or her health. In this sense, relative deprivation may affect health

because it reflects the ability of affected individuals to access material goods and services that in turn promote well-being. This underscores the futility of distinguishing material from psychosocial effects of income – any effect of income on health could be simultaneously operating through material as well as psychosocial pathways.

Income Inequality and Health

The community-level analog of relative deprivation leads us to the idea of income inequality, which can be stated as:

$$h_{ij} = f(I_j, y_{ij}) \quad (5)$$

where I_j refers to summary measure of income distribution (e.g., the Gini coefficient) for community j in which the individual resides. Income inequality and relative deprivation are conceptually related because, as income inequality rises, those at the bottom end of the distribution become more relatively deprived. Various measures are available to quantify the extent of income inequality in a given community or society; of these, the Gini coefficient is frequently used. Algebraically, the Gini coefficient is defined as one-half of the arithmetic average of the absolute differences between all pairs of incomes in a population, the total then being normalized on the mean income. If incomes in a population are distributed completely equally, the Gini value is 0; and if one person has all the income (the condition of maximum inequality), the Gini is 1.0. The Gini coefficient can also be illustrated through the use of Lorenz curve (Figure 1). On the horizontal axis, the

Figure 1 Lorenz curve.

population (in this case, households) is sorted and ranked according to deciles of income, from the low-est-decile group to the top-decile group. The vertical axis then plots the proportion of the aggregate income within that community accruing to each group. Under conditions of perfect equality in the distribution of income ($Gini = 0$), each decile group would account for exactly 10 percent of the aggregate income and the Lorenz curve would follow the 45° line of equality. In reality, the Lorenz curve falls below the 45° line of equality because the bottom groups in the income distribution earn considerably less than their equal shares. In [Figure 1](#), for instance, the bottom one-half of households accounts for just 20% of the aggregate income. The degree to which the Lorenz curve departs from the 45° line of equality is a measure of income inequality. As it turns out, the Gini coefficient is the ratio of the area between the Lorenz curve and the 45° line of equality (A) and the area of the triangle below the 45° line of equality (A + B).

There is some debate as to whether income inequality is a valid community analog of relative deprivation at the individual level. Some argue that Gini coefficient is the measure of relative deprivation. For instance, the relative deprivation curve that represents the gaps between an individual's income and the incomes of all individuals richer than him or her (as a proportion of mean income) turns out to be the Gini coefficient. Others have presented a generalization of Gini, the s-Ginis, that can be interpreted as indices of relative deprivation. Indeed, it has been stated that "the Gini coefficient may be interpreted as a transformation of an index of 'envy' evaluated through the comparison of the income of an individual and that of all other individuals richer than him/her" (Atkinson and Bourguignon, 2000: 43).

As mentioned earlier, the relationship between individual income and health status is concave, such that each additional dollar of income raises individual health by a decreasing amount. The concave relationship between income and health has important implications for the aggregate-level relationship between income distribution and average health achievement, as noted by Rodgers. As illustrated in [Figure 2](#), in a hypothetical society consisting of just two individuals – a rich one (with income x_4) and a poor one (with income x_1) – transferring a given amount of money (amount $x_4 - x_3$) from the rich person to the poor person will result in an improvement in average health (from y_1 to y_2) because the improvement in the health of the poor person more than offsets the loss in health of the rich person. Indeed, it is possible that, by transferring incomes from the relatively flat part of the

Figure 2 The individual-level relationship between income and health.

income–health curve, there may be no loss in health for the wealthy person.

Consequently, researchers have posited that an aggregate relationship between the average health status of a society and the level of income inequality in a society could be observed if the individual-level relationship between income and health (within the society) is concave. That is, the aggregate relationship between income inequality and health may be observed simply due to the underlying concave functional form of the individual income–health relationship and assuming an x amount of transfer of money from rich to the poor. Indeed, such a transfer also implies a reduction in the income inequality level in that particularly society, and as such, the society with the narrower distribution of income will have a better average health status, all other things being equal. It is worth emphasizing that, if the relationship between income and health at the individual level is linear (not concave), then a transfer of income from the rich to the poor will reduce the level of income inequality but will not lead to improvements in the average health status of that society.

Occasionally, this expected relationship between income distribution and the average health status of a population (which is a direct function of the concave relationship between individual income and health) has been described as a statistical artifact of the concave relationship between individual income and health. The use of the term artifact is misleading here because it suggests that the potential for improving the health of the poor through income redistribution is a statistical illusion. Indeed, there is nothing artifactual about improving the health of the poor (and hence, average population health) through income and wealth redistribution – indeed the success of much philanthropy (e.g., donating money to provide vaccines to the world's poor) rests on the validity of this assumption.

In addition to the concavity effect just described, researchers have posited an additional contextual effect of income inequality on health. This is the hypothesis that the distribution of income in society, over and above individual incomes as well as societal average income, matters for population health such that individuals (regardless of their individual incomes) tend to have worse health in societies that are more unequal. Thus, income inequality *per se* may be damaging to public's health by causing a *downward shift* in the income–health curve. Thus, the income inequality hypothesis is viewed as an independent contextual effect akin to a social pollution effect.

Income and Health: The Role of Social Comparisons

Wilkinson argued that income inequality is harmful to health because it leads to invidious social comparisons among individuals in society and that these comparisons, in turn, may act as a stressor in the form of feelings of shame, anxiety, and social exclusion and, as such, impact physiological systems. The economist Juliet Schor described how widening inequalities have given rise to a culture of upward social comparisons (and the attendant frustration of aspirations). Thus, a mechanism linking income inequality to health involves psychosocial pathways that have adverse physiological consequences. Models of the direct effects of stress on physiological systems include allostatic load, which describes the wear and tear on the organism caused by exposure to daily adverse life circumstances. Stress may also affect health indirectly by leading to a more adverse profile of behaviors, such as smoking and excess drinking. This line of explanation links the community income inequality and individual health through individual relative deprivation (including those related to income). Researchers interested in adult health and mortality have argued that inequality worsens adult health through social comparison. They have argued that income inequality affects health because ranking low in the social hierarchy produces negative emotions such as shame and distrust that lead to worse health via neuroendocrine mechanisms and stress-induced behaviors such as smoking, excessive drinking, and drug use. Although the human body is remarkable in adapting to occasional bouts of stress, they have argued that cumulative exposures to stressors (such as chronic poverty, low socioeconomic status, and constant social comparisons) eventually result in strain on regulatory systems.

Although we have discussed here the role of social comparisons as a source of stress, there are other

mechanisms that link income and health that can also be explained through stress-based explanations. For instance, a chronic exposure to unpredictable social and economic circumstances (associated with low income) can also be a source of stress in addition to inhibiting access to important material goods necessary to sustain desirable levels of well-being. The challenge for researchers on income and health is to elucidate the specific pathways through which the different conceptualizations of income may impact on health through differential types of stressors.

Introduction

Stress in Unacculturated Indigenous Societies

Stress and Acculturation in Indigenous Societies

Stress and Migration

Conclusion

Glossary

<i>Acculturation</i>	The process by which a society is culturally influenced by another society.
<i>Culture-bound syndromes</i>	Local idioms for the expression of distress, consisting of socially recognized illness categories that have no acknowledged counterpart in Western biomedicine.
<i>Cultural consonance</i>	The degree to which an individual approximates in his or her own behavior the prototypes for behavior encoded in shared cultural models.
<i>Extended kin support systems</i>	Systems in which help or assistance is most appropriately sought from individuals who are related by common ancestry or marriage.
<i>Indigenous societies</i>	Societies that are native to a particular locale, in which people speak a distinctive language and have a distinctive social heritage and which are often technologically less complex. Usually, the way of life of the people is on the periphery of the

major world industrial societies. Indigenous societies can also be referred to as traditional societies.

Modernization

A special case of acculturation in which an indigenous society is undergoing economic change or development.

Status

incongruence

A discrepancy between an individual's aspirations for social status or prestige and his or her resources for actually achieving those aspirations.

Introduction

An indigenous or traditional society is characterized as native to a specific region, with a distinctive language and way of life. Also, the way of life of the people is peripheral to global capitalist market systems. This does not mean that such a society is unaffected by global market systems; in fact, one major source of stress in indigenous societies is the impact of economic change emanating from those larger systems. Nor does this mean that an indigenous society cannot be embedded within a modern, industrial society (e.g., Native Americans). Rather, in an indigenous society, culture and related systems of social organization are structured more in terms of local context and local systems of meaning, and less in terms of the middle-class values of industrial society. Understanding stress and its effects in indigenous societies requires an examination of both social arrangements that generate stresses within the indigenous social structure and the way in which traditional culture and social structure interact with outside influences to generate stresses.

Stress in Unacculturated Indigenous Societies

Anthropologists conventionally describe the relative degree of external influence on a society or community along a continuum of acculturation. A society that is relatively unacculturated or traditional has been minimally influenced by processes of modernization. Usually this means that households tend to practice a mix of economic pursuits for subsistence (i.e., raising food directly for consumption within the household) and for exchange in local markets. With respect to material lifestyles, although there is some access to imported consumer goods, these often are primarily related to subsistence activities (e.g., agricultural implements, outboard motors). Most goods consumed by a household are produced locally. What wage labor exists is usually within the community, and there is little formal education. Social relationships tend to be dominated by kinship. Systems of kinship can range from large groups formed around descent from a common ancestor (or unilineal descent groups) to somewhat more loosely structured kindreds that are like large ego-centered social networks. Finally, belief systems reflect local meanings and understandings, even when there have been modernizing influences (e.g., missionaries).

Patterns of morbidity and mortality within traditional societies provide one clue to patterns of stress in those societies. Generally speaking, rates of high blood pressure, coronary artery disease, stroke, and cancer tend to be very low. In traditional societies, patterns of morbidity and mortality tend to be dominated by infectious and parasitic disease, especially in childhood, and by trauma in adulthood. Although any generalizations must be tempered by reference to local ecological conditions, in many traditional societies life expectancy beyond 5 years of age is comparable to life expectancy in industrial societies, and in the aged in these societies there is little evidence of the kind of pathologies (e.g., atherosclerosis) associated with aging in industrial societies.

What has been most illuminating in the study of stress in unacculturated societies is the study of culture-bound syndromes. Culture-bound syndromes are local idioms of distress. They can be thought of as culturally appropriate ways of experiencing and expressing distress arising from stressful social relationships. Some attempts have been made to equate the culture-bound syndromes with Western psychiatric diagnoses, but recent evidence indicates that there is not a direct correspondence between culture-bound syndromes and biomedical psychiatric diagnoses; it is probably more useful to think of

culture-bound syndromes and Western psychiatric diagnoses as comorbid.

A classic example of a culture-bound syndrome is *susto* in Latino societies of Central and South America. The individual suffering from *susto* experiences a loss of energy, difficulty in maintaining customary activities, frequent spells of crying, and diffuse somatic symptoms such as loss of appetite and sleep disturbance. As the name in Spanish implies, *susto* is attributed to a sudden fright (e.g., seeing a snake), at which time the soul of the individual leaves the body and wanders freely.

Research has shown that the distribution of *susto* is socially patterned. The prevalence is higher in females, tends to increase with age, and tends to be higher in relatively poorer communities. Furthermore, the greatest risk of *susto* has been found among persons experiencing difficulty in enacting common social role expectations. This usually arises from a lack of specific kinds of social resources (e.g., not having a large kinship network) that can be called on in carrying out expected role obligations (such as contributions to community work groups). Similar findings have been obtained in research on other culture-bound syndromes such as *ataques de nervios* in Puerto Rico, *debilidad* in the Andean highlands, heart illness in Iran, and *nervos* in Brazil. Culture-bound syndromes occur when individuals are low in cultural consonance; that is, they are unable to approximate in their own behaviors the prototypes for behaviors that are encoded in widely shared cultural models.

The experience of a culture-bound syndrome is important in two respects. First, it makes meaningful and intelligible the experience of social stress both to the person suffering the stress and to his or her social network. Second, in many societies, there are cultural practices, including healing rituals and participation in religious organizations, that deal directly with the syndrome and the underlying difficulties in social relationships. The aim is to mend the tear in the fabric of social relationships and hence end the individual's suffering.

The existence of these beliefs and practices that are helpful in ameliorating cultural stresses may in part account for patterns of morbidity and mortality in indigenous societies. As noted previously, the diseases conventionally associated with stress in industrial societies are relatively less important in indigenous societies. Also, in most cases an increase of blood pressure with age is not observed in indigenous societies. Other patterns of disease distribution that are taken for granted in industrial societies are not

observed in traditional societies. One of the more striking of these is the association of blood pressure with African descent ethnicity. While it is assumed that persons of African descent have higher blood pressures, in fact this is true primarily for those of African descent in the Western hemisphere, and more specifically in societies in which Africans had formerly been enslaved. So, for example, when communities of African descent are compared, communities in Africa have the lowest average blood pressures, communities in the West Indies have intermediate average blood pressures, and African American and African Brazilian communities have the highest average blood pressures. Recent findings show also that *quilombo* or refugee communities descended from escaped slaves in isolated areas of Brazil have low average blood pressures and exhibit little increase of blood pressure with age.

These patterns suggest two things. First, there may be a relatively higher level of social integration in indigenous societies, along with practices that help to moderate the impact of social stressors, that account for the lower prevalence of conditions and diseases associated with stress in industrial societies. Second, the process of social change leading to the modern industrial state may itself generate profound social stresses that contribute to the distinctive pattern of morbidity and mortality in those societies.

At the same time, it is important not to romanticize life in indigenous societies, in the sense of overemphasizing social integration and cohesion, because stresses will be generated within any system of social relationships. What is important to specify across different cultural contexts is the process by which social stresses are generated and the ability of indigenous support systems to deal with those stresses.

Promising results in this regard are emerging from research on hormones and neurotransmitters associated with the stress process. Newer techniques of data collection under difficult field conditions, along with techniques for the analysis of those data, are beginning to show how variation in social behavior within traditional societies is associated with inter- and intra-individual variation in stress hormones, which in turn is associated with acute illness. For example, research in a peasant village in the West Indies has shown that men who are perceived by their peers to emulate the ideals of manhood in this community have lower circulating levels of cortisol. Similarly, children growing up in families that are closer to the cultural ideal of the family have lower circulating cortisol levels and experience fewer acute illnesses. This research, coupled with research on local idioms of distress, suggests that stresses in

unacculturated societies are deeply embedded in the system of social relationships that organizes everyday life.

Stress and Acculturation in Indigenous Societies

Societies that are undergoing acculturation are those that are being influenced by other social and cultural systems. In the study of stress and disease, the effect of modern industrial societies on local sociocultural systems has been of particular interest. There is considerable imbalance in this type of acculturation, because of the unequal power and influence that modern industrial states exert on traditional societies. The terms modernization and development have been used to describe this kind of influence.

Modernization in traditional societies was initiated by colonial expansion and has been particularly prominent since World War II and related processes of globalization. This influence has not been inadvertent. The aim has been to take advantage of both physical and social resources in developing societies.

These changes have had large effects on local social systems, including a transition from subsistence occupations to wage labor occupations, the replacement of indigenous languages by European languages, increased urbanization, increased emphasis on formal education, decreased emphasis on traditional social relationships, especially kinship, and substantial changes in indigenous belief systems. Everyday life can change at a rapid pace in modernizing contexts, the result being a stressful lack of consonance between traditional culture and the demands of modern life.

Specific and general aspects of this modernization process have been found to be associated with increasing rates of chronic diseases. Urbanization has been found to be associated with increasing rates of hypertension, independent of changes in diet and physical activity. Some investigators have used summary measures of acculturation both for individuals and for communities. When communities are ranked along a continuum of traditional, intermediate, and modern (depending on aggregate characteristics of the population by the variables noted previously), rates of hypertension, obesity, diabetes, and coronary artery disease consistently increase in communities with higher levels of acculturation or modernization. Also, daily circulating levels of hormones such as cortisol appear to increase in association with acculturative stress.

The results have been somewhat less consistent using measures of acculturation operationalized at the level of the individual. The pattern can still be

observed in many studies, but the strength and the consistency of the associations are not as great. This has led some researchers to speculate that the linear model of stress and acculturation is not specified well enough to describe the process at the individual level.

Because the general model of stress and acculturation has not worked very well at the level of the individual, researchers have adapted the stress model, as it has been developed for European and American populations, and applied it to communities experiencing change and development. A major challenge in this research has been to identify factors that generalize across different cultural contexts and to distinguish those from factors that are culturally specific. There is emerging evidence to suggest that at least one set of social stressors generalizes across modernizing societies, primarily because these stressors are generated by the modernization process itself. In most societies undergoing modernization, there is an increased availability of Western consumer goods. Frequently the ownership of these goods becomes highly valued as symbols of status or prestige, often supplanting traditional indicators of higher status. This by itself contributes to the climate of change in a modernizing community. In addition, however, aspirations for the lifestyles of the Western middle class can quickly outstrip the ability of a developing economy to provide the kinds of jobs and salaries necessary to maintain such a lifestyle. Therefore, a kind of status incongruence can occur, in which the desire to attain and maintain a Western middle-class lifestyle exceeds an individual's economic resources for such a lifestyle. This kind of status incongruence has been found to be related to psychiatric symptoms, high blood pressure, elevated serum lipids, the risk of diabetes, and immunological status in developing societies in Latin America, the Caribbean, and Polynesia.

Resources for coping with stressors have been found to be more culturally variable. Social support systems are a good case in point. Social support can be defined as the emotional and practical assistance an individual believes is available to him or her during times of felt need; the social network in which this assistance is available is the social support system. In research in Europe and North America, generally speaking, emphasis has been placed on the nature of the assistance or social support transactions, rather than on who might provide that assistance. There is a growing body of cross-cultural research indicating that, in many societies, who provides the assistance is critical in determining the relationship between social support and health. This is probably a reflection of a

continuing importance of kinship in defining who is and who is not an appropriate individual with whom to enter into a social relationship.

For example, in Latin American societies people have traditionally lived in large extended families organized around a father and his married sons (known as a patrilineal extended family). In addition to these extended family relationships, there is a social practice known as *compadrazgo*, through which individuals, especially men, establish formal, kinship-like relationships with unrelated persons (known as fictive kinship). The term *compadrazgo* literally means co-parenthood, and this carries the expectation of mutual support. These ties of fictive kinship are used to establish economically and politically important alliances. Research has shown that men who perceive greater amounts of support from both their extended and their fictive kin have lower blood pressures. Women are expected to restrict themselves to the household and domestic duties. Not surprisingly, with respect to health status, women benefit primarily from support available within the household. These studies show that the definition and effects of social supports are closely related to cultural and social structural factors and can only be understood within that context.

Other forms of stress resistance show similar differences cross-culturally, although the evidence is not quite as consistent as with social support. For example, in European and North American studies, a direct action coping style has been found to be helpful in moderating the effects of stressful events or circumstances. In this style of coping, attempting to directly confront and alter stressful circumstances contributes to better health status. In some research in traditional societies, this same relationship has been observed. In others, the opposite effect has been observed, i.e., a direct action coping style actually exacerbates distress and poor outcomes. In the specific case of this coping style, this probably has to do with the actual resources available to individuals and families in coping with stressors. When social and economic resources are meager at best, the belief that an individual can truly change the circumstances that are often thrust upon him- or herself may, in the long run, be deleterious.

A major source of stress in societies undergoing modernization is the increase in socioeconomic inequity that accompanies modernization. Generally speaking, the distribution of wealth becomes more unequal, resulting in marked social stratification, whereas previously such stratification was, if not absent, at least muted. Recent studies point to the effects of such stratification on cultural consonance as a

potent source of stress. The capacity of an individual to achieve higher cultural consonance is severely compromised by lower socioeconomic status. Lower cultural consonance has been found to be associated with higher blood pressure and psychological distress and to mediate the effects of socioeconomic status in contexts of modernization. The inability to act on these widely shared cultural models is a potent source of stress in developing societies.

Stress and Migration

The other way in which social and cultural change can influence indigenous communities is through migration. This century has seen remarkable movements of people from traditional societies to North America and Western Europe, along with internal migration within developing societies that takes migrants into cosmopolitan urban centers in their own societies. Rarely can migration be considered an individual matter. Rather, it is much more common for entire communities of migrants to become established in their host country. This usually occurs because migration follows patterns established through social networks, especially kinship networks. Individuals and households take advantage of kin-based social support systems established in host countries in order to establish themselves there.

Research suggests that a similar pattern of stress and response develops in cases of migration like that observed in developing societies. That is, migrants come to the new setting with aspirations for a new life, aspirations that are reinforced in host countries through the depiction of middle-class lifestyles in advertising and other media forms. At the same time, migrants typically occupy the lowest levels of socioeconomic status in their host countries. Therefore, the ability of the migrant to amass the economic resources necessary to achieve a middle-class lifestyle is severely compromised. This status incongruence again has been found to be associated with chronic disease risk factors such as blood pressure and glucose levels.

Patterns of social support that can help an individual to cope with this kind of social stressor will often again be found in the kin support system. There are, however, several additional complications. First, kin support systems will often be fragmented. Only some people will migrate, not entire support systems. This can mean that some households and individuals are socially isolated, lacking even the most basic social supports. This can also mean that a large burden can be placed on a support system that is fragmented, and that the resulting demands for support are simply too

much for the system to bear. Second, the migrant, especially to North America, is entering a highly competitive and individualistic society. The kinds of mutual rights and obligations entailed by kinship have ceased to be recognized as strongly, for example, in the United States as in traditional societies in Latin America or Southeast Asia. Therefore, in some specific situations, the kin support system can come to be a source of stress and tension, as opposed to a resource for resisting stress.

The complications entailed here are illustrated by migrants from Samoa to northern California. Traditionally organized into large extended kin groups represented by chiefs, Samoans have transplanted their social organization to some U.S. urban centers. Traditionally, the chief (or *matai*) controls economic decision making for the entire extended family. In the American urban setting, however, the economic demands of daily life for an individual household can conflict with the decisions made for the extended family, causing this traditional form of social organization to become a source of stress. At the same time, within the larger extended family, core systems of kin-based social support have emerged, especially involving networks of adult siblings. Individuals and households with a strong support system of this kind have better health status in spite of social stressors such as status incongruence. This specific case illustrates the importance of understanding the adaptation of migrants in a host society in relation to their traditional cultural context, as well as the demands of the new social setting.

Some research on migrants from the developing world has shown the long-term effects of major life events experienced by families in the society of origin. This has been observed in immigrants from Latin America and Southeast Asia who have been exposed to protracted civil war and related conflicts. For example, it was found that persons who had had relatives kidnapped or murdered by nonmilitary death squads in Guatemala had continuing high levels of anxiety and depression years after the event. Similarly, anxiety and depression levels in migrants from Southeast Asia to the United States were associated with time spent in refugee camps, independently from other stressors and demographic control variables. These major crises associated with large-scale political events and circumstances can have effects that continue well after the initial, acute stages.

Conclusion

The study of stress and indigenous societies has helped to illuminate various aspects of the stress

process. Perhaps the most important has been the clear demonstration of the link between the stress process and the social and cultural context in which individuals and families live. When stressors and resistance resources are examined only within a single cultural context, it can appear as if individual differences in exposure to stressors or in access to resistance resources are the only key to understanding the process. What is lost is the recognition that what counts as a stressor or a resistance resource is itself a function of the cultural context and related social influences. Furthermore, the relationship between stressors, resources, and outcomes can also be modified by social and cultural context. Comparing the stress process in different cultural contexts has been integral to revealing this aspect of the process.

Future research must be explicitly comparative in scope in order to expand on findings produced thus far. For example, research in developing societies suggests that the most important stressors in those societies are actually a function of the development process itself, such as status incongruence. Put differently, this aspect of the stress process is comparable across different settings. On the other hand, the most important resources for resisting stress appear to be specific to the local setting, as in the way in which systems of social support are structured by the existing systems of social organization. Continuing to refine these studies, including better measurements of the physiological dimensions of stress, will increase our understanding of human adaptation.

Process of Industrialization and Epidemiological Transition
Stressful Social Environments and Health
Concluding Remarks

Glossary

<i>Epidemiological transition</i>	The changing pattern of most prevalent diseases from infectious to chronic degenerative diseases.
<i>Formal rationality</i>	The purposeful calculation of the most efficient means to achieve a goal where rational choices are made to maximize individual benefit.
<i>Gender roles</i>	The cluster of social expectations and norms guiding typically male vs. typically female behavior.
<i>Health-related lifestyle</i>	A collective pattern of health-promoting or health-damaging behavior based on routinized choices people make about food, exercise, hygiene, safety, relaxation, and so on. This pattern is structured by specific needs, social norms, and constraints.
<i>Social disintegration</i>	A weakening of social ties and an absence of cooperative exchange resulting in a lack of social rules and trust and, ultimately, in a breakdown of a social order.

Process of Industrialization and Epidemiological Transition

The industrial revolution started in Great Britain during the second half of the eighteenth century and has subsequently spread across a number of economically advanced countries. This revolution, together with the political revolution initiated in France, must be considered one of the most radical changes in human history. Within a very short time period, fundamental ways of living and working were transformed from a basically agricultural society to a society that is driven increasingly by technology and market economy. With the invention of engines and machines, productivity was increased in an unprecedented way.

A large part of the workforce, employed formerly as peasants and craftsmen, moved to urban areas to engage in unskilled or semiskilled work. The rapid growth of cities and the formation of an industrial workforce contributed to two subsequent, most significant demographic trends: (1) a take-off period of population growth with declining infant mortality rates and (2) a decline in fertility with slow population growth in combination with increased life expectancy. At the same time, the social institutions of marriage and family underwent a marked transformation, and a new division of labor between the sexes started to develop.

After severe poverty and economic exploitation in the early stages of industrial capitalism, economic progress and the development of a welfare state were experienced by a growing proportion of industrial populations. This progress included the availability of healthier food, increased opportunities of energy consumption, better housing, transport, education, and general hygiene. In terms of population health, the process of industrialization was associated with a marked increase in life expectancy and a change in the pattern of prevailing diseases. Overall, 2 to 3 years are added to life expectancy at birth with each decade passing in advanced societies. This increase cannot be attributed to the fact that people, once becoming older, live substantially longer than in previous generations. Rather, increases in life expectancy were, and still are, mainly due to a reduction of death rates at earlier ages and, thus, to increased probabilities of survival. The most substantial decline has been in infant mortality, followed by reductions in childhood and midlife mortality. A dramatic reduction in mortality from infectious diseases played a major role in this process. The typical pattern of leading causes of disability and death in advanced societies is characterized by chronic conditions such as coronary heart disease, cancer, stroke, accidents, and metabolic and mental disorders. This change is referred to as the epidemiological transition.

While the development of modern medicine and related improvements of health care are a direct outflow of the broader processes of industrialization and modernization, it has been demonstrated that the impact of medicine on this major change in the pattern of morbidity and mortality has been limited. In fact, the bulk of the decline in mortality from infectious diseases came before medicine had developed effective forms of treatment and prevention. This means that public health measures and factors related to a general

rise in living standards may have accounted for this change more significantly than medicine.

With this epidemiological transition from infectious to degenerative diseases, medicine and public health face new challenges. A substantial part of these challenges directly or indirectly concerns, the impact of stressful social environments on health. The following section discusses three different aspects of this impact in more detail.

Stressful Social Environments and Health

Stressful Experience and Health-Related Lifestyles

Many of the aforementioned degenerative diseases are considered diseases of affluence because they were prevalent to the extent that life became more comfortable. For instance, with technological advances and with the expansion of commercially available food and drugs, a number of behavioral health risks were programmed, e.g., access to a car reduced physical activity significantly, and, more importantly, it also increased the number of injuries and deaths from accidents. Frequent consumption of fat and meat, at first available to the wealthier groups, contributed to elevated blood lipids, overweight, and associated health risks. Spending money on drugs such as cigarettes or alcohol increased the risk of cancer and heart disease, among others. Consequently, during the first stage of the epidemiological transition, these behaviorally induced risks associated with a wealthier lifestyle were more prevalent among socially and economically privileged groups. At a later stage of the process of industrialization and modernization, however, this social pattern changed: diseases of affluence increasingly became the diseases of the poor. In contemporary societies, this is clearly the case in almost all northern, western, and central European countries, in the United States, and in Canada. The same pattern may be experienced in the near future in countries that are currently exposed to a process of rapid industrialization.

Hence, substantial social inequalities in health are observed, mainly due to higher rates of the former affluent diseases among lower socioeconomic groups.

To explain this shift in the social distribution of a broad range of degenerative diseases and their behavioral risk factors (e.g., smoking, alcohol consumption, overweight, hypertension, metabolic disorders, cardiovascular diseases, some manifestations of cancer, AIDS), the concept of health-related lifestyle needs to be described more precisely.

Health-related lifestyles are collective patterns of health-promoting or health-damaging behavior based on routinized choices people make about food, exercise, hygiene, safety, relaxation, and so on. In many cases, these choices form a coherent pattern that is structured by specific needs, attitudes, and social norms and by the constraints of a group's socioeconomic condition. Once established among a sociocultural group, such behavioral patterns may be transferred from one generation to the next through socialization processes or they may be adopted by model learning from peer groups during adolescence. Unfortunately, the latter is often the case with respect to health-damaging behaviors (smoking, alcohol and drug consumption, unsafe sex practices, etc.). As these behaviors are experienced as relief and reward in stressful psychosocial circumstances they may be reinforced easily and, thus, trigger careers of addiction later in life.

Alternatively, with higher levels of education and knowledge and with the availability of alternative means of coping with stressful psychosocial circumstances, health-damaging lifestyles may be abandoned more easily. This is most probably what happened to the wealthier populations in advanced societies in the recent past and what contributed, and still contributes, to the widening gap in life expectancy between socioeconomic groups.

To date, there are still powerful constraints toward maintaining health-damaging lifestyles among less privileged social groups. A major constraint concerns the exposure to adverse living and working environments. A large number of epidemiologic studies document associations between the amount of exposure to these unfavourable circumstances and the prevalence of unhealthy behavior. For instance, with respect to cigarette smoking, conditions such as heavy workload, shiftwork, social isolation at work, and job instability were identified. Moreover, people who suffer from unfavorable social comparison, e.g., regarding education, income, or general social standing, are at risk of exhibiting a health-damaging life-style. In all these cases, relief and reward experience in terms of some form of addictive behavior may be needed to mitigate a stressful experience.

Some of these processes operate in more subtle ways. It is well known that the processes of primary socialization vary considerably according to the parent's socioeconomic status. In particular, children born into families with a low educational level face more difficulties in deferring their gratifications and in pursuing long-lasting goals in future life. Their sense of self-efficacy and self-esteem is low, and they are more likely to experience their environment as

uncontrollable and fateful. Thus, when facing frustrations, they may be less capable of coping in an active, effective way. Rather, they may seek relief in passive behavior, including drug consumption and related health risks.

This knowledge, derived from sociological and psychological research, has direct implications for health promotion activities and the design of preventive programs. It is evident that comprehensive approaches tackling structural and individual conditions are needed to change health lifestyles in a successful way.

Unfortunately, influential economic interests operate in almost all advanced societies to counteract these measures, most evidently the tobacco and alcohol industry. Advertising activities in mass medias and diffusion of new fashions through opinion leaders are effective means to maintain drug consumption. Efforts to equalize gender roles and to assimilate female attitudes and activities to behaviors that were typical attributes of the traditional male gender role resulted in an unprecedented increase in cigarette consumption among young women. Moreover, women in recent years, as compared to the 1950s, are more likely to work in occupations that were once almost exclusively male. As a consequence of these large-scale societal changes, some of the most advanced industrial societies, such as the United States, are moving toward greater equality in mortality between the sexes.

Impact of Social Disintegration on Health

Industrialized societies are characterized by a high level of mobility. A substantial part of this mobility is due to migration. Economic constraints and wars are the major causes of large migration waves that have shaped the life of many generations throughout the processes of industrialization and modernization. Social mobility is a second component of these secular trends. As mentioned briefly, the onset of early industrialization in Europe and the United States has been facilitated by a broader sociocultural development of modernization that promoted formal rationality and individualism as the dominant modes of thinking and behaving in western societies. Formal rationality is the purposeful calculation of the most efficient means to achieve a goal. Rational choices are made to maximize individual benefit. With the expansion of individual rights, duties, and life chances, traditional ways of maintaining group solidarity, social norms, and obligations lost their significance and attraction. Individual striving for an improved standard of living has become the dominant motivation

overriding traditional social constraints. Thus, a large proportion of people was, and currently is, subject to intragenerational social upward (and downward) mobility in occupational life.

For a long time, social mobility and increased individualism were considered the ultimate benefits of modernization, as legitimized by substantial gains in the quality of life. However, more recently, awareness of the limits, risks, and possible health adverse effects of this development has been growing. One line of thinking along these lines concerns the negative effects on health produced by social disintegration.

Social disintegration is an often reported consequence of enhanced social mobility and related gain in individual freedom. It becomes manifest through a weakening of close social ties (e.g., among family members) and a decrease in reciprocal social exchange or solidarity. Under these conditions, the stability of social relationships is threatened, and commitments held among affiliates may lose their significance. Social disintegration is often associated with a state of social anomie, i.e., a lack of rules and orientations guiding interpersonal exchange. In a society characterized by anomie, individual behavior cannot be predicted by social norms any longer as these norms have lost their validity.

A growing number of investigations conducted by social epidemiologists and medical sociologists document adverse health effects among people who experience social disintegration. Lack of social cohesion or social support, shrinking social networks, and elevated proportions of societal members suffering from social isolation, social exclusion, or individual struggle are different facets of this general trend. For instance, in a cross-cultural perspective analyzing data from 84 different societies, one study concluded that with greater involvement in a money economy a systematic increase in mean blood pressure was evident, even after adjusting for important confounders such as salt consumption and body mass index. With greater involvement in modern money economy, individual competition and striving for benefit became dominant at the expense of cooperative social relationships. In a review of more recent investigations it was concluded that at least eight community-based prospective studies in industrialized societies reveal an association between social disintegration and mortality rates, usually death from all causes. In particular, mortality risks are elevated among people who lack social ties to others. Even at a more distant, macrosocial level, current evidence suggests that a decline in overall mortality, now familiar in most advanced societies, is prevented in an economy that is maximizing

shareholder profit at the expense of investments into community life, culture, and social security.

Although the precise mechanisms that transform stressful experience resulting from social disintegration into increased susceptibility to fatal or nonfatal bodily disease are far from clear, impressive evidence is available from social experiments in mammals. It illustrates the critical role of rewarding and securing experiences that social exchange, affiliation, and affection play in regulating the body's basic physiological processes. It may well be that the cultural canon of modern industrialized societies heavily weighted toward formal rationality, control, and individual striving substantially diminishes the health gain associated with progress in human evolution. This latter conclusion is supported further by a third line of investigation focusing on the impact of modern working life on health.

Stress at Work and Health

The most profound change evoked by the process of industrialization concerns the nature of human work. For a large part of the workforce, work and home become two different places and two different types of social organization. In all economically advanced societies, work and occupation in adult life are accorded primacy for the following reasons. First, having a job is a principal prerequisite for continuous income and, thus, for independence from traditional support systems (family, community welfare, etc.). Increasingly, the level of income determines a wide range of life chances. Second, training for a job and achievement of occupational status are important goals of socialization. It is through education, job training, and status acquisition that personal growth and development are realized, that a core social identity outside the family is acquired, and that goal-directed activity in human life is shaped. At the same time, occupational settings produce the most pervasive continuous demands during one's lifetime, and exposure to harmful job conditions is an important determinant of disability and premature death in midlife.

The nature of work has changed dramatically over the past hundred years. Industrial mass production no longer dominates the labor market. This is due, in part, to technological progress, in part to a growing number of jobs available in the service sector, and, most importantly, in person-based service occupations and professions. In this latter case, unlike in the industrial sector, the potential of rationalization and related cut down in personnel is limited. However, even within industrial work, major changes have taken place. With

less focus on physically strenuous work, with improved safety measures against chemical and physical hazards at work, and with more demands for psychomentally stressful jobs (e.g., information processing, controlling, coordinating activities, often performed under time pressure) new health risks emerged. Meanwhile, there has been a recognition that the importance of work for health goes beyond traditional occupational diseases as there is growing evidence of adverse health effects produced by psychomentally and socio-emotionally stressful jobs.

Before describing these health risks briefly, additional important changes in occupational life need to be mentioned. They are related to the structure of the labor market. There has been an increasing participation of women in the labor market, an increase in short term or part-time working and other forms of flexible job arrangements, and, most importantly, an increase in job instability and structural unemployment. This latter trend currently hits the economically most advanced societies as well as economies that lag behind. Overall, a substantial part of the economically active population is confined to insecure jobs, to premature retirement, or to job loss. Loss of job, as well as continued experience of job insecurity, was shown to be associated with an elevated risk of mortality in a number of prospective studies. In view of the rather high prevalence of these labor market conditions, the adverse effects on health produced by the economy are obvious.

Even within a continuously employed workforce, exposure to stressful psychosocial work environments carries the risk of ill health. Examples of this latter trend are shift work, irregular working hours and overwork, social isolation at work, conflicting demands, lack of control, and monotony. People working in jobs that are defined by a combination of at least some of these characteristics are at risk of developing chronic disease conditions such as hypertension, coronary heart disease, low back pain, or depression at least twice as often compared to people working in more favorable jobs. Additional evidence documents substantially elevated health risks among workers and employees who suffer from an imbalance between high efforts spent at work and low rewards received in terms of money, esteem, or promotion prospects. In many cases, such unfavorable job conditions are maintained, e.g., due to lack of alternatives in the labor market.

Concluding Remarks

In conclusion, despite substantial progress in life expectancy and the standard of living, the process

of industrialization in technology, science, economy, and sociopolitical development has produced a substantial health burden that is attributable to an increasingly stressful social environment. Three aspects of this development were analyzed: (1) the impact of psychosocially adverse circumstances on health-damaging lifestyles; (2) health risks associated with social disintegration; and (3) afflictions of stressful working life and labor market conditions on well-being and health. It seems unlikely that these trends will be diminished in the near future as the process of economic and sociocultural globalization is progressing at a high pace. Moreover, pressures originating from population growth in rapidly developing parts of the world, new socioenvironmental risks, and man-made disasters may aggravate rather than moderate this burden. At the same time, with scientific progress in understanding the determinants and dynamics of stress-related health risks and with new worldwide public health efforts evolving, there is still hope that modernization and industrialization of human societies result in a sustainable humane and more healthy future.

Discussion and Conclusion

Glossary

<i>Adrenocorticotropic hormone (ACTH)</i>	A secreted serum factor from the adrenal glands that is considered a stress hormone.
<i>Cytokines</i>	Soluble proteins secreted by one type of cell that interacts and activates immune cells.

Legionella pneumophila

An opportunistic bacterium that causes Legionnaire's disease and primarily infects macrophages, a class of immune cells responsible for host resistance to infectious diseases.

Lentiviruses

A retrovirus, such as human immunodeficiency virus, that primarily infects immune cells and can induce acquired immunodeficiency syndrome.

Opportunistic infections

Infections caused by otherwise lowly pathogenic microbes in individuals who have some immunodeficiency.

Respiratory viruses

Small microorganisms that preferentially infect the cells of the respiratory system.

Introduction

Stress is a major factor in the progression of infectious diseases in humans as well as in experimental and domestic animals. In this regard, it is now known that the central nervous system (CNS), the endocrine system, and the immune system are complex systems that interact with one another. In particular, the brain and CNS exert a profound effect on the immune

system, including mechanisms necessary for resistance to microbial infection. Stress dysregulates the immune response by affecting the interplay of these systems. New knowledge developed during the last few decades through experimental and clinical studies provide evidence that many immune alterations are due to stressful events that provoke health changes. Stressors, including specific stressful events, can stimulate the activities of the hypothalamic-pituitary-adrenal (HPA) axis as well as the sympathetic nervous system to enhance an individual's ability to adapt physiologically in response to a threat (Figure 1). Furthermore, psychological stress ensues when events or environmental demands exceed an individual's perceived ability to cope. Stress can increase susceptibility to infectious agents, influence the severity of infectious diseases, diminish an immune response to a vaccine, reactivate a latent herpesvirus, and in general depress resistance to opportunistic infectious organisms that otherwise should not cause overt disease. Moreover, stressful events and the stress they evoke also may substantially increase the production of pro-inflammatory cytokines associated with a wide range of diseases, especially chronic immune diseases.

Not only the CNS is complex; there is now much new knowledge about the complexity of the immune

system, which consists of both cellular and humoral elements. Many immune responses are mediated by soluble factors such as cytokines produced by lymphoid cells and by factors important for control of the CNS, including steroids and various neuropeptides and neurohormones produced by neuronal cells (Figure 1). Important mechanisms whereby stress influences susceptibility or the more rapid progression of infectious diseases are becoming clearer because of new experimental and clinical studies by investigators worldwide. Specifically, the current explosion of new knowledge concerning the nature and mechanism of the immune response system has focused attention on the important role of various lymphoid cells for resistance versus susceptibility to microbes, especially intracellular pathogens such as opportunistic bacteria, viruses, fungi, and even parasites. It is now known that the brain and CNS in general have profound effects on immunity. The interaction between the brain and immune system entails a complex series of activities involving responses of many cells to multiple stimuli.

Central Nervous-Immune-Endocrine System Interactions

The modulation of the immune response by the CNS is mediated by a complex network of bidirectional interactions between the nervous, endocrine, and immune systems. The HPA axis and autonomic nervous systems provide two key pathways for immune system dysregulation. For example, stress may activate the sympathetic adrenomedullary (SAM), as well as the HPA axis, and thereby result in the release of pituitary and adrenal hormones, including catecholamines (epinephrine and norepinephrine), ACTH, cortisol, growth hormone, and prolactin, which are influenced by stressful events, including negative emotions. Each of these soluble factors results in quantitative and qualitative changes in immune activity. For example, external factors, including stress, increase cortisol levels, which may induce adverse immunological alterations. Immune cells express receptors for one or more factors associated with the HPA and SAM axes, generally called hormones. Immunomodulation by hormones occurs through two pathways: directly, through binding to a specific cell receptor, or indirectly, by the induction of cytokines such as interferon (IFN- γ), interleukins (ILs), and pro-inflammatory cytokines such as tumor necrosis factor (TNF- α). Such cytokines interact with various target cells. Furthermore, the interaction between the CNS and the immune system is bidirectional. For example, immune cell-derived ILs such as IL-1 affect the production of corticotropin releasing hormone

Figure 1 Arrangement of the hypothalamic-pituitary-adrenal and sympathetic adrenomedullary systems. The central noradrenergic system is activated in parallel with the peripheral sympathetic nervous system, and it is the central nervous system counterpart. The cerebral catecholamine system (i.e., dopamine and epinephrine) is activated under stress. ACTH, adrenocorticotrophic hormone; CNS, central nervous system; CRH, corticotropin releasing hormone; PNS, peripheral nervous system.

(CRH) by the hypothalamus in the brain. An increase in stress hormone levels results in the further dysregulation of immune function. Similarly, lymphocytes produce many hormones such as ACTH, prolactin, and growth hormone.

Resistance to microbes, including bacteria, viruses, and parasites, depends on both innate and adaptive immune responses, consisting of a variety of cell types such as T and B lymphocytes; phagocytic monocytic cells, such as dendritic cells and macrophages; neutrophils; and polymorphonuclear cells. Soluble factors produced mainly by lymphoid cells, including ILs, IFNs, and other cytokines, are essential for host resistance. Immune resistance is based on primary and secondary antibody responses and cell-mediated immunity due to T lymphocytes such as Th1 effector and Th2 helper cells, as well as Th3 regulatory cells. Such cells produce the many humoral factors important for immunoregulatory and protective pro-inflammatory activity, especially to intracellular opportunistic microbial pathogens.

Stress Hormones and Infections

As already indicated, many types of signals to the brain (e.g., visual, tactile, and emotional) cause the hypothalamus to release CRH, and, in turn, this stimulates the pituitary gland to release ACTH into the circulation, which then stimulates the adrenal cortex to produce glucocorticoids. ACTH inhibits the response of lymphocytes to antigenic or mitogenic stimulation, depresses cytokine responses by lymphocytes, and suppresses natural killer (NK) cell activity and antibody responses to a variety of antigens, including those associated with microorganisms. It is widely recognized that increased glucocorticoid production is by no means the only response to stress. The levels of several neuropeptides, including vasoactive intestinal peptides, substance P, prolactin, and growth hormones are increased, as are catecholamines such as epinephrine and norepinephrine. Localized increases in catecholamine levels probably account for the suppression of lymphocyte responses to mitogens or antigens. The immune system also returns signals to the CNS to close this circle. As previously stated, immune cells synthesize a number of neuropeptide hormones, including ACTH and β -endorphin. Moreover, cytokines produced by lymphocytes and macrophages have effects that are signals to the brain. Various ILs, including TNF- α , stimulate the hypothalamus, resulting in the induction of fever and release of corticosteroid hormones. Receptors for neuropeptides are present on lymphoid cells (Table 1), and neuropeptides derived from neural or immune cells stimulate leukocytes (Tables 2–3).

Table 1 Receptors for neuropeptide hormones on cells of the immune system^a

<i>Hormone</i>	<i>Receptor site</i>
ACTH	Rat spleen T and B cells
β -Endorphin	Rat spleen T and B cells
Calcitonin gene-related peptide	Rat spleen T and B cells
CRH	Human PBL
Growth hormone	Rodent spleen, thymus, human PBL
Growth hormone-releasing hormone	Rodent spleen, human PBL
Luteinizing hormone-releasing hormone	Rat thymocytes
Prolactin	Human and mouse T and B cells
Somatostatin	Human PBL
Substance P	Mouse T and B cells
Thyrotropin	Human neutrophils, monocytes, B cells

^aACTH, adrenocorticotrophic hormone; CRH, corticotropin releasing hormone; PBL, peripheral blood leukocytes.

Table 2 Stimuli for leukocyte-derived peptide hormones^a

<i>Hormone</i>	<i>Stimulator</i>
Arginine vasopressin	Unknown
Corticotropin and endorphin	Newcastle disease virus Lymphotropic viruses Bacterial lipopolysaccharide CRH Arginine vasopressin IL-1
Follicle-stimulating hormone	Con A
Growth hormone	Growth hormone-releasing hormone Growth hormone
Luteinizing hormone	Luteinizing hormone-releasing hormone
Metenkephalin	Con A
Neuropeptide Y	Unknown
Parathyroid hormone-related protein	Human T-cell lymphotropic virus
Prolactin	Con A
Somatostatin	Hypersensitivity
Substance P	Unknown
Thyrotropin	Staphylococcal enterotoxin A Thyrotropin-releasing hormone
Vasoactive intestinal peptide	Histamine liberators Hypersensitivity

^aCon A, concanavalin A; CRH, corticotropin releasing hormone; IL, interleukin.

Many studies have shown that increases in stress, especially those resulting in increased levels of stress hormones such as corticosteroids, alter the susceptibility of experimental animals to infectious diseases significantly (Table 4). The study of effects of

Table 3 Modulation of immune responses by neuropeptides^a

Neuropeptide	Immune response
Arginine vasopressin	T-cell helper function
Corticotropin	Functions for IFN- γ production
	Antibody synthesis
	IFN- γ production
Endorphins	B-lymphocyte stimulation
	Antibody synthesis
	Mitogenesis
	NK-cell activity
Growth hormone	Cytotoxic T-cell activity
	Mitogenesis
Growth hormone-releasing hormone	Inhibit NK-cell activity
	Inhibit chemotactic response
Luteinizing hormone	Cytokine formation
Prolactin	IL-2 receptor production
Somatostatin	Reduces IFN- γ production
Substance P	Stimulate chemotaxis
	Stimulate proliferation
	Modulate cytokine levels
Thyrotropin	Antibody synthesis
	Co-mitogen
	Co-mitogenic with Con A

^aCon A, concanavalin A; IFN, interferon; NK, natural killer.

Table 4 Effect of glucocorticoids on microbial immunity^a

Organism	Glucocorticoid effect
<i>Bordetella pertussis</i>	Promotes initial protective effect, then promotes microbial survival
<i>Candida albicans</i>	Exacerbates infection
<i>Escherichia coli</i>	Decreases inflammation but not bacterial clearance
<i>Legionella pneumophila</i>	Exacerbates infection
<i>Listeria monocytogenes</i>	Increases susceptibility, impairs monocyte function
<i>Mycobacterium avium</i>	Impairs macrophage function
<i>Mycobacterium leprae</i>	Alters IFN- γ effects on monocytes
<i>Mycobacterium tuberculosis</i>	Increases cellular infiltration, increases bacterial growth
<i>Neisseria gonorrhoeae</i>	Increases infection rate
<i>Plasmodium berghei</i>	Decreases parasitemia
<i>Pneumocystis carinii</i>	Increases susceptibility
<i>Propionibacterium acnes</i>	Exacerbates infection
<i>Pseudomonas aeruginosa</i>	Increases susceptibility
<i>Staphylococcus aureus</i>	Ameliorates IP route infection
<i>Streptococcus faecalis</i>	Increases resistance
<i>Trichinella spiralis</i>	Decreases nematode clearance, cellular infiltration
<i>Yersinia pestis</i> (<i>Pasteurella pestis</i>)	Increases invasive infection, bacteremia

^aIFN, interferon; IP, intraperitoneal.

neuroendocrine-immune interactions on microbial pathogenesis and immunity during the course of infectious disease is an important area of interdisciplinary research, and various studies showed that

physiological stress and psychiatric illness can compromise immune function and alter susceptibility to infectious agents (Table 5). It is widely known that patients with psychiatric disorders, including schizophrenia and even depression, are more likely to have infectious diseases. This may be associated with altered HPA activity or physiological dysfunction related to immunomodulation associated with drugs that affect the brain. Unconventional life styles, eating disorders, poor hygiene, and other factors associated with severe mental health problems may contribute to altered immune function. In this regard, it is now recognized that the recreational use and abuse of illegal drugs such as marijuana, cocaine, heroin, and other opiates, as well as more widely used legal substances such as alcohol and tobacco, have marked effects on the CNS and the immune system. Individuals who use these drugs frequently are more susceptible to opportunistic microorganisms. The detrimental effects of such abused drugs on immunity in both humans and animals have now been extensively studied. These drugs are known to increase corticosteroid levels in both humans and experimental animals, either at the time of addiction or during withdrawal, and this effect has been related to altered immune resistance to microbial infection. Addiction to a psychoactive substance (as in the stimulation of the HPA axis) induces enhanced adrenal corticosteroid secretion, followed by consequential increases in serum glucocorticoids and the activation of the sympathetic nervous system. These responses result in immune dysregulation and increased susceptibility to microbial infections, especially to opportunistic pathogens.

Numerous early clinical observations reported that individuals often become more susceptible to infections following stressful situations. However, the concept of stress was not defined sharply. A stressor was often defined as any type of external or internal challenge, visual, tactile, or emotional, that disrupts the physiological equilibrium or homeostasis of an individual. For example, a number of studies showed that infection by mycobacteria, which cause tuberculosis, is increased by stress.

Alterations in the susceptibility to other opportunistic bacteria, as well as to viruses and parasites in general, have been studied extensively. Increases in infections due to stress occur not only in human populations but also in farm animals and experimental animals. There is now a large body of biomedical literature showing that stress alters susceptibility to infection. The mechanism of the stress includes effects on humoral function such as the production of glucocorticoids. The effects of stresses on two types

Table 5 Effects of stress on microbial immunity

Pathogen	Animal species	Stressor	Effect
<i>Escherichia coli</i>	Chicken	Cold	Increases resistance
	Chicken	Social	Increases resistance
<i>Hymenolepis nana</i>	Mouse	Predator	Increases reinfection rate
<i>Mycobacterium avium</i>	Mouse	Restraint	Increases susceptibility, impairs macrophage function
<i>Mycobacterium tuberculosis</i>	Rabbit	Tumbling	Increases susceptibility
<i>Plasmodium berghei</i>	Mouse	Electric	Increases survival
<i>Salmonella enteritidis</i>	Chicken	Fasting	Decreases antibody response
<i>Salmonella typhimurium</i>	Mouse	Crowding	Increases susceptibility

of infective diseases, bacterial and viral, are discussed next as examples.

Bacterial Infections and Steroids

Legionella pneumophila, an opportunistic ubiquitous bacterium, is the causative agent of Legionnaire's disease. Although almost all individuals are exposed to *Legionella*, only a small percentage of individuals exposed to these organisms are infected clinically. Indeed, when *Legionella* was first discovered in the outbreak of Legionnaire's disease in Philadelphia in the late 1970s, most of the 2500 conventioners exposed to this organism from the air conditioning system in the Bellevue Stratford Hotel developed significant titers to these bacteria. However, only approximately 200 individuals became clinically ill, and a significant number of these people died. These individuals had certain factors associated with their susceptibility, including increased alcohol consumption, cigarette smoking, (in general) being older, and being more immunocompromised. It is now well recognized that *L. pneumophila* causes clinical infection mainly in immunocompromised individuals, including patients who are treated with immunosuppressive drugs in hospitals for cancer chemotherapy or for organ transplantation.

Increases in susceptibility to infection by *Legionella* associated with steroid use have been studied in detail (Table 4). Although steroid therapy for various diseases has had revolutionary therapeutic effects and is widely recognized as constituting a major success for modern medicine, it is often associated with serious side effects; steroids have both beneficial and nonbeneficial features, and these may be inseparable. The anti-inflammatory and immunosuppressive activities of steroids are considered essential for the therapy of certain diseases, including autoimmune diseases, and to prevent organ rejection following transplantation. However, steroids may also result in an increased susceptibility to infections, especially by an opportunistic bacterium such as *L. pneumophila*. Although the spectrum of microbes causing infections in patients

during steroid therapy is not completely clear, experimental animal studies showed that steroid treatment is associated with increased infections caused by certain groups of opportunistic bacteria, including *Legionella*. The general consensus concerning the mechanism whereby steroids induce altered susceptibility to bacterial infection is that steroids suppress the immune response system.

The most important host defense mechanism against invading intracellular opportunistic bacteria is phagocytosis by macrophages, followed by intracellular killing and digestion of the microbes. It is now clear that steroids suppress the number and function of macrophages and neutrophils (Figures 2–3). For example, experimental studies have shown that peritoneal macrophages from hydrocortisone-treated mice are more susceptible to infection and killing by *L. pneumophila in vitro*. The steroid-involved impairment of antimicrobial activity by macrophages from mice infected with *Legionella* is generally similar to that reported for *Listeria monocytogenes*. For example, *in vivo* treatment of mice with hydrocortisone acetate affects the ability of peritoneal macrophages from the animals to kill *L. pneumophila in vitro*, as well as other microorganisms such as *Listeria monocytogenes*, *Streptococcus pyogenes*, *Staphylococcus aureus*, *Staphylococcus epidermidis*, *Escherichia coli*, and *Pseudomonas aeruginosa*.

The treatment of macrophages with steroids *in vitro* may affect antimicrobial immunity directly. For example, the ability of macrophages treated with steroids to kill *L. pneumophila* and organisms such as *Staphylococci in vitro* is markedly reduced. The specific mechanisms involved in the steroid impairment of macrophages, however, are unclear. In general, the intracellular killing of bacteria and other microbes by macrophages requires lysosomal migration to and fusion with the microbe-containing phagosome. It is probable that the mechanism of the steroid-induced impairment of antimicrobial activity of monocytes or macrophages is associated with the stabilization of lysosomes by steroids, which prevents their fusion with phagosomes. However, the possibility exists that

Figure 2 The effect of steroids on macrophages and monocytes. Glucocorticoids have a direct action on the number and function of phagocytic cells, including cytokine production and receptor expression. ↓, decrease; GC, glucocorticoid; IL, interleukin; TNF, tumor necrosis factor.

Figure 3 Prevention of neutrophil accumulation at local inflammatory site by steroid treatment. The chemotactic activity of neutrophils from steroid-treated animals or humans was enhanced, inhibited very weakly, or unaffected, except for neutrophils from inflammatory exudates, which showed reduced chemotactic activity. ↓, decrease; ↑, increase; ↔, minimal or no change; FcR, Fc receptor; GC, glucocorticoid.

steroids induce the impairment of the antimicrobial activity of macrophages by suppressing the synthesis of one or several specific proteins of the killing system of the phagocytes. Nevertheless, several observations have indicated that macrophages treated with steroids ingest microorganisms at a normal rate and, after phagocytosis, secrete the usual reactive oxygen intermediates and exhibit normal fusion of lysosomes and phagosomes (i.e., the oxidative killing systems). Steroid-treated macrophages react to a cytokine such as IFN and are normally primed to secrete reactive oxygen intermediates on challenge. Thus, there have been reports negating the likelihood there is a direct

deleterious effect of steroids on the antimicrobial activity of macrophages.

Virus Infections and Stress

Virus infection can be exacerbated by stress hormones such as cortisone. For example, hydrocortisone-treated mice show an increased susceptibility to challenge with viruses such as influenza virus, Coxsackie virus, or even mouse hepatitis virus. Peritoneal macrophages from cortisone-treated mice are almost 1000 times more susceptible to challenge with the mouse hepatitis virus *in vitro* than are macrophages from

untreated mice. Resistant macrophages from normal mice succumb to cytolysis by mouse hepatitis virus when cultured with spleen cells from cortisone-treated mice but not with spleen cells from normal mice, suggesting that a soluble product from lymphoid cells may be involved in increased susceptibility of the macrophages due to steroids.

Various studies have reported the association between naturally occurring stresses and individuals' susceptibility to upper respiratory tract viral infections. Although most of these studies provide some support for the hypothesis that stress is associated with an increased risk of upper respiratory viral infections, it is not yet clear how this occurs. Longitudinal studies performed with large populations of individuals suggest that stress is a significant factor in increasing the susceptibility to viral infection.

A number of studies have been performed testing the possibility that stress is involved in experimentally induced upper respiratory tract viral infections. Psychologically stressed, experimentally infected individuals had significantly higher levels of upper respiratory tract infections, but there were no differences in the incidence of infections or the amount of shed virus in nasal secretions between these and unstressed individuals. Several studies reported that stress precedes the onset of upper respiratory tract viral infection episodes, especially in children; for example, several studies reported a significant increase in minor stresses a few days before the onset of upper respiratory tract infection symptoms. The likelihood exists that the severity of the symptoms of upper respiratory tract infections rather than the incidence of infection may be affected by different types of psychological stress. So far, it is apparent that more clinical studies must be performed before we can fully understand the relationship between stress and upper respiratory tract viral infections in patient populations. In addition, little is known about how the timing of the stressor and viral exposure influences the development of these infections. There is some evidence suggesting that stress occurring after experimental viral exposure may increase susceptibility; however, there are differing published findings, some indicating an increased and some a decreased susceptibility even when stress precedes viral exposure.

Studies have been reported concerning stress and progression of acquired immunodeficiency syndrome (AIDS) in human immunodeficiency virus (HIV)-positive subjects. For example, a study published by investigators from the University of Miami School of Medicine, supported by the National Institute of Mental Health, showed that HIV-positive high-risk subjects had less evidence of progression to clinical AIDS when psychological intervention techniques,

such as stress reduction by counseling, music therapy, or exercise, were used. This study supported the view that psychological stress in HIV-positive individuals can result in a more rapid progression to clinical AIDS and that psychological stresses were often related to lack of an effective support system and with the notification of HIV-positive status. Such findings suggested that psychological stress and its intervention may be associated with the progression of chronic life-threatening viral infections, such as HIV.

There are also well-known studies concerning the effects of stress on herpesvirus exacerbation. A landmark study performed at the Ohio State University Medical School reported that medical students taking a routinely scheduled examination had increased psychological stress immediately preceding the examination and that this was associated with decreased immune function and the increased recurrence of herpesvirus titers, indicative of the reactivation of the herpesvirus. The study was particularly well controlled, consisting of medical students who were generally healthy and immunologically mature (i.e., approximately the second decade of life). All the students had normal immune functions, but at the time of the examination they were shown by psychological tests to have a significant stress level and increased serum glucocorticoids. Simultaneously, they showed a decrease in an immune function important in resistance to viral infection, NK cell activity and T-cell levels. Many of the students had an exacerbation of latent herpes shortly after the examination (with its associated stress).

Note that temporal relations often cannot be controlled readily in population studies. Furthermore, little is known about the differential effects of acute (short-term) versus chronic (long-term) or repetitive stressors. The clinical literature suggests that chronic stress may have particularly strong pernicious effects on health. But it is difficult to undertake true experimental studies of stress exposure in human populations because it is difficult to randomly assign subjects to defined stressor conditions. Although challenge viral exposure in experimental studies appears to be relatively controlled, it is often not because of independent variables and because stress is difficult to assess and manipulate. Furthermore, little is known about the biological pathways that may be responsible for the association between stress and increased viral infection in patient populations.

The effect of psychosocial interventions in ameliorating a number of infectious problems in patients with diseases as diverse as cardiovascular disease and cancer is currently being investigated. Many investigators believe that appropriate psychosocial intervention may result in reduced stress and thus

reduced viral infections. Nevertheless, most studies to date with patient populations and viral infections suggest only that there is an association between stress and increased susceptibility to infection.

Discussion and Conclusion

It is now widely accepted that stress plays an important role in altering the susceptibility to infectious agents such as bacteria, viruses, and even parasites. Furthermore, stress is also acknowledged to be involved in increasing the susceptibility to the progression of autoimmune diseases and malignancies. Many studies have suggested that the stress hormones, especially cortisone and ACTH, are important in altering the immune mechanisms, especially in the lymphoid cells, which are important in the resistance to opportunistic microorganisms such as intracellular bacteria and viruses.

Various studies showed that a variety of stressors increase the susceptibility of experimental animals to bacterial infections. Some of the most defined studies to date were performed with mycobacteria, organisms that cause tuberculosis in humans and in domestic and experimental animals. Infection by mycobacteria is known to be increased by stress; for example, a number of widely known studies showed that mice that were normally resistant to mycobacterial infection showed increased susceptibility when given certain stressors. This has been related to increases in glucocorticoid levels, which are known to affect lymphoid cell function.

Glucocorticoids produced by the adrenal cortex under the influence of ACTH from the pituitary gland in the brain affect both humoral and cellular immune responses. Mice treated with glucocorticoids often show increased cellular infiltration following infection with mycobacteria and increased growth of the bacteria. Glucocorticoids have been shown to increase the susceptibility of experimental mice to infectious agents such *Listeria monocytogenes* and *Pneumocystis carinii*. However, glucocorticoids promote the survival of *Bordetella pertussis*, the causative agent of whooping cough in humans, although initially this hormone provides some protection against challenge infection. Furthermore, cortisone ameliorates infection by *Staphylococcus aureus* in experimental animals, but has been reported to increase the susceptibility to *Pseudomonas aeruginosa* in humans and animals and also to exacerbate infection by the ubiquitous fungus *Candida albicans*. Thus, there is a marked variability in the effects of corticoids on infection, depending on the organisms involved; the reasons for this remain unknown. For example, various studies showed that infection with

Propionibacterium acnes is exacerbated by corticosteroids but that infection with *Streptococcus faecalis* is decreased by them. Furthermore, animals infected with *Plasmodium*, the cause of malaria, showed decreased parasitemia due to corticosteroids.

It is clear that corticosteroids decrease the accumulation of neutrophils at a local inflammatory site. Such neutrophil accumulation is important in clearance of or resistance to bacterial infection. It has also been reported that the chemotactic activity of neutrophils from steroid-treated animals or humans can be enhanced, inhibited very weakly, or unaffected; however, most studies showed that neutrophils obtained from inflammatory exudates in steroid-treated mice showed reduced chemotactic activity. Such data indicate that the poor accumulation of neutrophils in inflammatory sites may be mediated by the inhibition of the release of local chemotactic factors rather than a direct effect on neutrophils. This possibility seems likely because steroid treatment does not inhibit neutrophil accumulation induced by the injection of a chemotactic complement component into human skin. It has been demonstrated that the treatment of purified human neutrophils with the synthetic steroid deoxymethasone does not inhibit neutrophil chemotaxis in response to a range of concentrations of known chemoattractants.

There are several mechanisms for gene regulation by the steroid-receptor complex. Glucocorticoid response elements regulate the rate of transcription initiated by promoters of the corresponding glucocorticoid response genes. Another possible regulation mechanism is the interaction with DNA-binding proteins associated with regulatory elements of DNA, such as the glucocorticoid modulatory element protein. Thus, it appears that steroids regulate the transcription of certain genes coding for proteins that augment steroid effects.

The infection of animals with the ubiquitous bacterium *L. pneumophila* is modulated markedly by steroids. Thus, steroid levels are an important factor in the increased susceptibility of organ-transplant patients, who are often immunosuppressed with steroids prior to the transplant and thus may become more susceptible to an opportunistic infection such as *Legionella* in hospitals. Viral infections have also been shown to be exacerbated by stress hormones, including cortisone. It is well known that hydrocortisone-treated mice show an increased susceptibility to challenge with a variety of viruses, including influenza virus, Coxsackie virus, and mouse hepatitis virus. It seems likely that, because stress is often associated with increased corticosteroid levels only, changes in the level of this hormone may be related to the apparent increased susceptibility of individuals to an upper respiratory tract viral infection following a

stressful event. Results obtained using animal models show an increased susceptibility to challenge infection with bacteria or viruses, and studies of humans, infected either naturally or experimentally, strongly suggest a relationship between stress-induced immunomodulatory hormones and increased susceptibility to infection.

The complex interrelationship between the nervous and the immune system parallels the association of the susceptibility or resistance to infections by various microorganisms under conditions of stress. This is even more likely because it is known that the immune response is modulated markedly by a wide variety of neuropeptides associated with the CNS, not only corticotropin but also other hormones such as endorphins, prolactin, growth hormone, vasopressin, and somatotrophin. Neuropeptides affect a wide variety of immune responses, including antibody formation, mitogenic responses of lymphocytes, cytotoxicity by T cells, NK cell production and activity, and cytokine production. Thus, neuropeptides, hormones, and their receptors, present not only in the CNS but also on immune cells, are important factors in immunomodulation related to altering the susceptibility to infection by microorganisms, especially intracellular opportunistic bacteria and viruses. However, because of the complexity of both the CNS and the immune system, it is difficult to isolate the various pathways that are important in this altered susceptibility to infection associated with stress. Further studies in numerous laboratories, including those mainly concerned with the neurological system and those concerned with infectious diseases and immunity, will undoubtedly provide a greater understanding of the role of stress in infection.

Inflammation and Sepsis

Summary

Glossary

Apoptosis

A process of cell death that results from the activation of specific signaling pathways that lead to the intracellular disruption of mitochondrial integrity, activation of cascade of proteases (e.g., caspases), and cell disintegration while maintaining the cell membrane intact.

Chemokines

A family of polypeptides that comprises about 50 members and 20 different receptors. This family of polypeptides is all involved in leukocyte traffic. Their diverse biological actions include interactions with viruses and cell receptors in numerous tissues.

Chemotaxis

The orientation and movement of a cell along a specific chemical concentration. Positive chemotaxis denotes movement of the cell toward the high-concentration site of the chemical; negative chemotaxis denotes movement of the cell away from the source of the chemical. Chemotactic properties are prevalent in all forms of leukocytes and in a wide variety of substances released in sites of tissue injury or activated cells.

Complement system

The entire functionality of approximately 20 distinct plasma proteins, their receptors, and ancillary/regulatory proteins that are responsible not only for immune cytolysis but also for reactions such as anaphylaxis, phagocytosis, opsonization, and hemolysis. Two major pathways for activation of the complement system are known: the classic pathway

Cytokines

in which all components C1–C9 participate in the reaction and the alternative pathway in which only part of the plasma factors participate along with others that are not essential in the classic reaction.

Nonantibody peptides and polypeptides that are released by activated cells (e.g., T cells) and transfer signals to other cells. Lymphokines (cytokines produced by lymphocytes) and monokines (cytokines produced by monocytes) are cytokines.

Inflammation

A localized protective response elicited by injury or destruction of tissues, which serves to destroy, dilute, or wall off (sequester) both the injurious agent and the injured tissue. It is characterized in the acute form by the classic signs of pain, heat, redness, swelling, and loss of function. Histologically, it involves a complex series of events, including the dilation of the arterioles and capillaries, extravasation of fluids, and migration of plasma proteins and leukocytes into the injured area.

Interleukins (ILs)

A generic term for a group of multifunctional cytokines that are produced by a variety of lymphoid and nonlymphoid cells. Originally believed to play a role only in leukocyte biology, ILs are now recognized as the products of diverse nonlymphoid cells that also act on diverse receptors on multiple cells outside the lymphoid system. Over 20 ILs have been identified to date that act via different receptors with large divergent and cross-activation among the IL family members. ILs are involved in many disease processes and are targets for promising drug discovery.

Leukocytes

Colorless blood cells capable of ameboid movement; they are capable of moving directionally in response to chemical stimuli (chemotaxis). Leukocytes are divided morphologically into granular cells (basophils, eosinophils, and neutrophils) and nongranular cells (lymphocytes and monocytes). Leukocytes are the primary cells that launch immune and inflammatory reactions. Leukocytes are present in the systemic circulation and in special lymphoid tissue such as the lymph node, bone marrow, and thymus.

Lymphocytes

Mostly mononuclear, nonphagocytic leukocytes found in the blood and

lymphoid tissue that make up the primary body of immune competent cells. Lymphocytes belong to two primary classes – T cells (thymus dependent) and B cells (Bursa dependent) – but several other subclasses with various functional and biochemical markers are known. Lymphocytes function via direct cell–cell interaction (specialized receptors) and via humoral mediators such as cytokines, interleukins, and chemokines as well as antibodies (a primary B-cell function). T cells are primarily responsible for cell-mediated immunity.

Mast cells

A connective tissue cell that elaborates highly reactive mediators such as cytokines, histamine, and enzymes, which can modulate matrix proteins such as chymotrypsin and tryptase. Mast cells (or mastocytes) are believed to play an important role in allergic rhinitis and asthma and, via enzymes released, to contribute to inflammation and atherosclerosis.

Matrix metalloproteinases (MMPs)

Zinc-dependent endopeptidases known for their ability to cleave one or several constituents of the extracellular matrix. MMPs consist of a large family of proteases that share common structural and functional elements.

Metabolic syndrome

A clinical condition that manifests four or five risk factors for cardiovascular and metabolic disorders. These include obesity, high glucose levels, high blood pressure, and aberrant plasma lipid levels (high triglycerides and low high-density lipoproteins).

Monocytes

Mononuclear phagocytic leukocytes that originate in the bone marrow. Monocytes are the source of tissue macrophages, which are abundant in lung and liver.

Nonsteroidal anti-inflammatory drug (NSAID)

Small organic (synthetic) chemicals that have been developed to suppress inflammation of various mechanisms, locations, and durations. They are commonly compounds that do not act like the steroid hormones (e.g., glucocorticoids). This class of medicines contains primarily inhibitors of the cyclooxygenase enzymes (which produce pro-inflammatory metabolites of the fatty acid arachidonate) and displays various proportional inhibitory capacities toward the cyclooxygenase 1 or 2 enzymes. Many such agents are marketed for pain relief from conditions such as arthritis and other muscular-skeletal conditions.

Sepsis

A condition that results from a harmful or host response to infection. Sepsis is marked by endotoxemia (the presence of bacterial or other toxins in the blood) and the activation of multiple systems such as the immune, cardiovascular, respiratory, coagulation, and complement systems. Sepsis can lead to multiple organ failure and death.

Introduction

Inflammation is a fundamental reaction of the body to injury. It is a complex biological phenomenon that comprises diverse cellular, neural, hormonal, and humoral systems. Inflammation involves the vascular system as well as blood-borne components linked via a complicated network of mediators. Inflammation can be the result of endogenous or exogenous injurious events. Inflammation is fundamentally viewed as a purposeful reaction aimed to repair, salvage, and restore the structure, function, and integrity of the injured tissue, organ, and organism well-being at large.

However, inflammation may also become a destructive or pathological condition that underlies numerous diseases in humans. Such diseases include bone and cartilage diseases (rheumatoid arthritis and osteoarthritis), skin diseases (psoriasis), central nervous system (CNS) diseases (multiple sclerosis and Alzheimer's disease), vascular diseases (atherosclerosis), cardiac diseases (heart failure and myocardial infarction), respiratory diseases (asthma and chronic obstructive pulmonary disease, COPD), gastrointestinal diseases (inflammatory bowel disease and Crohn's disease), and chronic unresolved infectious diseases (e.g., tuberculosis). In recent years, inflammation is increasingly recognized as a fundamental contributing element in many human diseases that have not been traditionally associated with inflammation. Conditions such as obesity, diabetes, metabolic syndrome, stroke, and cancer are all recognized as harboring various immune and inflammatory cells and mediators.

Inflammation is invariably linked to general homeostasis systems (e.g., coagulation and fibrinolysis) as also to the immune, complement, and the nervous system. As such, intervention in or modulation of specific pro-inflammatory mediators might result in broader consequences than the intended anti-inflammatory objective. Moreover, many mediators of inflammation are actually part of the normal physiological repertoire of molecules and cells that secure essential function and health. Therefore, the modulation (blockade or enhancement) of many recognized pro-inflammatory mediators, although

potentially to providing medical benefits, could also harm. Thus a fine balance needs to be preserved in many cases so as not to disrupt functionalities that require the same mediators to be at a level context and duration that, if not secured, could lead to pathological conditions on their own.

The advances made in understanding the cellular elements and mediators that initiate, propagate, and amplify various forms of inflammation have already yielded important therapeutics. Nonsteroidal anti-inflammatory drugs (NSAIDs), steroids, and, more recently, anti-cytokines and interleukin mimetics have an important role in the treatment of inflammation. It is, however, important to keep in mind that no anti-inflammatory therapeutic introduced into medical practice is free of adverse effect.

Immune and Inflammatory Cells in Acute Inflammation: Role of Endothelium and Adhesion Molecules

Acute injury to tissues, such as bruises, blunt-force trauma, or infectious agents, elicit a typical inflammatory reaction. The early response consists of local neurovascular reaction and release of preformed mediators that induced vasodilation, microvascular permeability, and extravasation of plasma components into the injured zone. This early stage is followed by the recruitment and migration of leukocytes from the systemic circulation with primary role of the polymorphonuclear (PMN) cells. The PMN cells are followed by monocytes, which together with the PMS cells and tissue macrophages provide the local tissue with the ability to conduct phagocytosis of invading pathogens, engulf cell debris (e.g., necrotic cells), and set the stage for tissue repair. The recruitment of leukocytes into the injury zone is governed by two key processes: chemotaxis and cell adhesion. The directional influx of leukocytes into the injured tissue is dependent on mediators such as chemokines or complement factors, which, along with cytokines and interleukins, also activate the leukocytes. In addition, the endothelium along the microvessels associated with the injury zone express adhesion molecules (in addition to constitutive ones) that enable the interaction with ligands that are expressed on the leukocytes. These cell adhesion molecules act as a cascade of events – from loose rolling, loose adhesion, committed adhesion, and final migration mostly through the endothelium junction. The key adhesion molecules are the vascular cell adhesion molecule (VCAM-1); intercellular adhesion molecule (ICAM-1), selectins (E, P, and L), and platelet-endothelial cells adhesion molecules (PECAMs).

Inflammation, Artherosclerosis, and Cardiovascular Diseases

The major pathological process that underwrites heart attacks, strokes, and peripheral vascular diseases is arteriosclerosis. Although the role of lipids (cholesterol in particular) in initiation and propagation of the arteriosclerotic pathology is well documented, inflammation is considered to be a major pathological feature in the evolution of this vascular disease. Lipid-loaded cells are the hallmark in any vascular atheroma, or plaque, which are macrophages (derived from blood monocytes) that phagocytosed modified cholesterol within lipoproteins particles. This process leads to the activation of the macrophages and release of cytokines, chemokines, interleukins, and other pro-inflammatory mediators such as arachidonic acid metabolites (lipoxygenase and cyclooxygenase). Apoptosis of excessively loaded macrophages (also called foam cells) is believed to release numerous inflammatory mediators that exacerbate the inflammatory process and increase the likelihood of its rupture. Most significantly in this regards are matrix metalloproteinases (MMPs; especially MMP-2 and -9), which are believed to reduce the fibrous cap of the atheroma and enhance plaque rupture, leading to the initiation of thrombosis and vascular occlusion. The atheromatous plaque is also rich in other inflammatory cells such a mast cells and T cells. The vascular inflammation part of the atherosclerosis process is viewed as an important therapeutic target and a component of the efficacy of major anti-atherosclerosis drugs such as the statins.

Inflammation and Cancer

A causal link between cancer and chronic inflammation has been demonstrated in the more than 1 million cancer patients linked to viruses and bacteria. Infection with human papillomaviruses, HCV, HBV; *Helicobacter pylori*; and Epstein-Barr virus are major risk factors for the development of cervical, gastrointestinal (GI), and hepatocellular cancer and lymphoma, respectively. The link between inflammation and cancer is not limited to infectious agents; chronic inflammation from cigarette smoke, asbestos, inflammatory bowel disease, silica, and so on contributes to the development of malignancy in the lungs, bladder, and GI tract. The activation of innate inflammation has been shown to contribute to cancer progression, including tumor necrosis factor (TNF)- α , and nuclear factor (NF)- κ B signaling. The disruption of the adaptive (or antigen-specific) immune response to tumors has been shown to be crucial to carcinogenesis. Many studies have documented the anergic antitumor

immune responses contrasting with the favorable prognosis conferred by the infiltration of tumors with cytotoxic killer T cells in several malignancies. In contrast, infiltration with supportive immune elements, such as growth-promoting macrophages, confers a worse prognosis in some malignancies. Finally, the association between multiple inflammatory biomarkers, such as interleukin (IL)-8, macrophage inflammatory protein (MIP)-1a, and various chemokines, whose expression levels correlate directly with worse prognosis, underlies the intimate relationship between inflammation and cancer development and progression.

Inflammation and Metabolic Syndrome

Metabolic syndrome emerges as the twenty-first-century epidemic that threatens both developed and less developed nations. Although the original concept defining metabolic syndrome focused on insulin resistance, namely, the poor responsiveness of target cells to insulin's ability to advance glucose metabolism, it has been recently recognized that inflammatory mediators are likely to be causally associated with the state of insulin resistance and, hence, metabolic syndrome. Most notable in this regard are the cytokines TNF- α , and IL-6. These cytokines, and primarily TNF- α , reduce the efficacy of insulin to enhance glucose uptake into the cells, a situation that manifests itself as hyperglycemia, a hallmark of the insulin resistant condition. Obesity, a key feature of the metabolic syndrome, is considered a pro-inflammatory state. Obesity is associated with increased oxidative stress, a biochemical condition prone to activating NF- κ B, NADPH, and other factors. Oxidative stress-induced inflammation increases endothelial leukocyte adhesion molecules that enhance leukocyte engagement with the endothelium, a primary step for their entry into the tissue, their activation, and the further release of inflammatory mediators. Excessive caloric intake, from carbohydrates or fats, is considered to significantly contribute to the inflammation state that drives key elements of metabolic syndrome.

Inflammation and Respiratory Diseases

Chronic obstructive pulmonary disease (COPD) is a chronic lung disorder that is mostly the result of smoking and other environmental toxic agents. The disorder is characterized by the accumulation of inflammatory cells such as macrophages and neutrophils, which are activated to release numerous mediators. The inflammation resides within the terminal bronchioles (small airways) and alveoli (small vesicular spaces where oxygen and CO₂ exchange takes

place). The persistent inflammation ultimately leads to the destruction of these pulmonary structures and respiratory failure. Prominent in the COPD pathomechanism are the inflammatory products of arachidonic acid and MMPs released by the activated inflammatory cells. MMP-9 and, in particular, MMP-12 play a predominant role in COPD by degrading the matrix proteins such as elastin, a matrix protein that is vital to the recoil of the bronchioles (small airways) and to alveolar health. MMP-12-mediated elastin degradation is believed to lead to emphysema, a state of destruction of the normal architecture of the lung respiratory elements. MMP-12 also plays a role in macrophage recruitment. Promising data emanating from recent research suggest that selective inhibitors of MMP-12 might be useful drugs in the treatment and prevention of COPD.

Bronchial asthma, a disease of lung airway spasm that leads to severe respiratory distress and severe forms to death, has strong inflammatory components. Arachidonic acid metabolites of potent inflammatory properties figure prominently in this disease. Lipoxigenase products called leukotrienes, prostanoids (prostaglandins and thromboxane A₂), and isoprostanes have been implicated in this disorder. Indeed, anti-inflammatory agents such as glucocorticosteroids have been a cornerstone of asthma-attack prevention, largely due to their inhibition of inflammatory eicosanoids. In addition, specific inhibitors of cysteinyl leukotriene have proven to serve additional therapeutic efficacy.

Inflammation and Joint Diseases

Several joint and bone diseases, such as rheumatoid arthritis and osteoarthritis, are probably the result of degenerative (the former) or immune and inflammatory (the latter) processes. Rheumatoid arthritis is a chronic systemic disease primarily affecting the joints in which severe chronic inflammation leads to the destruction of the joint structure and, ultimately, functional disability. Misdirected inflammation is the cardinal feature of rheumatological diseases. It involves both the initiation and maintenance phases of the disease, and the processes and players (cells and mediators) involved are similar to that in other diseases. Major cells in the immune system (i.e., neutrophils, macrophages, dendritic cells, B cells, and T cells) are the major culprits in the development and exacerbation of the disease. Although autoimmune mechanisms (including the generation of antibodies against joint tissue components) are believed to play a major causative role, the chronic condition is probably sustained by numerous inflammatory mediators, including cytokines, ILs, chemokines,

MMPs, prostanoids, and reactive oxygen radicals. Traditional anti-inflammatory agents such as the NSAIDs have been widely used to alleviate pain in and swelling of the joint, but their efficacy in mitigating the fundamental pathological process remained questionable. Likewise, the more recent class of anti-rheumatoid arthritis drugs, the COX-2 inhibitors, have a proven efficacy, yet at the cost of some increased risk for a cardiovascular adverse event. More recently, disease-modifying anti-arthritis drugs (DMARDs) have been successfully introduced into the medical management of rheumatoid arthritis. Such agents neutralize the cytokine TNF- α . Other cytokines and ILs (e.g., IL-6, IL-1, and IL-18) as well as interferon (IFN)- γ and endothelium leukocyte adhesion molecules (ICAM-1, VCAM-1, and selectins) are also targeted by therapeutic agents, as well as angiogenesis promoters such as vascular endothelium growth factor (VEGF).

The role of inflammation in osteoarthritis is less clear, although many of the cytokines already discussed are believed to play a key role in the destruction of bone and cartilage. Cartilage destruction probably involves cytokine activation of aggrecanase, an enzyme that destroys a major constituent of the normal cartilage.

Inflammation and Sepsis

Sepsis is a complex clinical syndrome that results from the harmful host response to infection; it results from the failure of the innate and acquired immune mechanisms to resolve the infectious condition and the damage induced by the toxins elaborated by the infectious agent. The bacterial toxins activate many of the inflammatory cells (in particular, neutrophils and monocytes/macrophages) but also other cells such as the endothelium. As a result of the toxins' action on the inflammatory cells, numerous preformed and newly elaborated mediators are produced, including oxygen radicals, bioactive lipid mediators, cytokines, chemokines, enzymes, and pro- and anticoagulation factors. Although many of the inflammatory cell products are helpful in confining and eliminating the infectious agent and its toxins, multiple tissues, organs, and system are also affected. Oxygen radical have bactericidal action, yet also affect the vasculature. Chemokines and cytokines modify the endothelium to support the fast recruitment of inflammation cells into the tissue to remove the invading agent while ILs activate and enhance the neutrophils, lymphocytes, and endothelium function. The inflammation cells also play a role in tissue repair and rehabilitation via the generation and release of growth factors that enhance

the regeneration of the damaged circulation, the matrix elements, and tissue integrity. The immune and inflammation cells and mediators are the most critical systems that secure defenses in sepsis. The failure of these defenses could lead to organ failure and death.

Summary

Inflammation plays a key role in acute injuries as well as chronic diseases. The immune and inflammatory reactions serve as the major defense mechanism against numerous external injurious events and pathological events that emerge as a result of endogenous aberrant genetic and biochemical imbalances. However, immune and inflammatory reactions can also evolve as a cause of diseases such as autoimmune diseases; granulomatous conditions; cancer; respiratory, joint, and bone diseases; and atherosclerosis. Thus, anti-inflammatory drugs emerge as an important source of novel therapeutics for diverse diseases such as cancer, metabolic syndrome, atherosclerosis, joint and bone diseases, and respiratory tract disorders.

Instinct Theory

R Gardner Jr

University of Wisconsin, Madison, WI, USA

This article is a revision of the previous edition article by R Gardner Jr., volume 2, pp 581–582, © 2000, Elsevier Inc.

The word instinct stems from a Latin root meaning impulse or instigation. Historically, the term differentiated innate from learned actions. Instincts were untaught, genetically preprogrammed, stereotypic, goal-directed behaviors and behavior chains shaped by natural selection. They exhibited more complexity than reflexes and occurred mostly in nonhuman animals. Nobel Prize-winning ethologist Konrad Lorenz described fixed motor patterns; releasers, the triggering stimuli of instinctive responses; and imprinting, wherein a newly hatched bird followed and attached

itself to any moving object located before it, replacing its mother.

The concept of inherited behavior remains important. However, Nikos Tinbergen, who shared the 1972 Nobel Prize with Lorenz, pointed out that the popular use of the term instinct has three meanings: (1) behavior driven from within (e.g., the mating instinct emerges in the spring), (2) nonlearned behavior (e.g., the newborn knows instinctively how to suckle its mother's nipple), and (3) unpremeditated behavior (e.g., the driver instinctively puts his foot on the brake). The term instinct, therefore, is often omitted in works of present-day ethologists, sociophysicologists, behavioral ecologists, and other workers in animal and human behavior.

Prior to the ethologists, the theoretician–psychoanalyst Sigmund Freud used the word instinct (also libido and drive) to carry forward his machine metaphors of

the mind (which had been popular in the nineteenth century), employing, for example, hydraulic and expended-fuel metaphors (as Lorenz also did for a time). Later John Bowlby, in contrast, defined instinct as behavioral-system actions that follow a recognizably similar pattern typical of the species, that have survival value, and that emerge even without the ordinary opportunities for learning.

Machine models hold little interest for modern theorists and researchers. Indeed, explosions of biological research on all fronts have rendered distinctions between learned and innate knowledge impossible. The capacity for learning is clearly inherited, a property that is expanded more in humans than in other animals. Moreover, research in molecular biology, notably in deciphering the genomes of many living forms, has demonstrated numerous conserved genes held in common by species, from bacteria to flies to fish to humans. Many influence behavior. Modern mammals exhibit reactions that ancestral vertebrates surely also had, for example, the flight-or-flight response.

Many anciently determined behaviors hinge on conspecific recognition and interaction (conspecifics are members of a same species), and these entail learning and behavioral modifications to varying extents. Certainly mating, social rank hierarchy, nurturance, eliciting nurturance, making in/out-group distinctions, and play behaviors must be included. These behaviors go awry in psychiatric disorders; examples include

1. Persecutory delusions, in which the patient has the conviction that he or she is targeted by hostile out-group members.
2. Mania, which involves the patient behaving in a commanding (dominant) fashion inappropriate for circumstances.
3. Depression, which involves the patient behaving like someone of low rank.
4. Paraphilias, which can be redefined as displaced mating urges.
5. Autism, in which children elicit nurturance poorly from parents and do not play spontaneously with other children.

Humans possess a brain three times heavier than their nearest relatives among the great apes, probably from greater sociality, which seems to enhance adaptation more than it costs in childbirth complications. However, 98.5% of primate genomes remain identical. Inherited neurons, altered to varying extents by experience, clearly determine all behaviors. Neuroscientist-psychiatrist Eric Kandel stressed that all learning reflects altered gene transcription and neuronal action. Learned behavior, once the antonym of instinct, now instead implies additional choices for the individual. Psychiatric leader Daniel X. Freedman noted that biological psychiatry is a redundancy; there is no unbiological psychology or sociology. All animal behavior, including human action, represents genetically programmed performances influenced by individual experience.

Hypnosis
Manipulative Therapies
Mindfulness-Based Stress Reduction
Relaxation Training
Conclusion

Glossary

<i>Acupuncture</i>	The insertion of thin needles at specific meridians or points in the body thought to affect the balance of the body's ability to manage pain and other medical illnesses, a practice originally developed in China.
<i>Homeopathy</i>	A treatment based on the idea that tiny amounts of substances can change the properties of water in a way that triggers the body's ability to respond to a disease.
<i>Hypnosis</i>	A state of highly focused attention, coupled with reduced awareness of experiences at the periphery of attention, and a heightened responsiveness to social cues.
<i>Integrative medicine</i>	The integration of many alternative or culturally sanctioned techniques into mainstream Western medical practice.

Introduction

While modern medical science has provided cures for many bacterial infections, life-extending treatments for viral infections such as HIV, and symptom-reducing interventions for heart disease, and has converted many kinds of cancer from a terminal to a chronic disease, it is especially striking that large numbers of Americans now turn to allied medical traditions and recently developed treatments for help with disease. More people than ever are living with serious illness, which is a chronic and severe stressor. Thus,

traditional medicine's very success has created a whole new set of problems. The acute disease model emphasizes diagnosis, definitive treatment, and cure. In some situations this works, but in many it does not. The leading killers of Americans, heart disease, stroke, and cancer, are by and large chronic and progressive rather than curable illnesses. The application of a curative model, in a setting in which disease management is often the most productive approach, leaves both doctors and patients frustrated. Rather than feeling satisfied when a disease is well managed, doctors and patients often feel disappointed that it has not been cured, and there is little emphasis on managing pain, anxiety, fatigue, and other debilitating aspects of illness and its treatment. The oldest adage of medicine is that our job is to "cure rarely, to relieve suffering often, and to comfort always." At the end of the twentieth century, it is as though that adage has been rewritten, that our job is now to "cure always, relieve suffering if one has the time, and leave the comforting to someone else."

Patients do indeed turn elsewhere for comfort. Complementary and alternative medicine professionals are one such place. They spend on average 30 min with their patients, compared with the typical 7 min allocated for physician–patient visits. Americans spend more out of pocket on complementary and alternative treatments than on visits to outpatient physicians or hospital care. An illness can be a lonely journey, and patients crave people who understand what the journey is like and who can stay with them during its course. Thus, the apparent appetite for complementary and alternative medicine is stimulated by the lack of help in coping with serious illness in modern medical care, which has become increasingly technological. This problem is being intensified by the business constraints in modern American medicine, which include frustration at obtaining appropriate reimbursement, increased paperwork burden, limited continuity of care, and second-guessing of treatment decisions. This can only further desiccate the doctor–patient relationship and limit the opportunities for medical compassion to enhance medical care.

Close to one-half of Americans utilize some form of alternative treatment, a substantial increase from the already sizeable figure of one-third in 1990. However, more than two-thirds of them utilize standard medical treatment as well, suggesting that as far as the patients are concerned, these interventions are complementary rather than alternative. A study in the

Kaiser health-care system indicated that the majority of complaints that lead to seeking alternative services are pain (52%) and anxiety (25%). Thus, patients seek complementary care for sensible reasons, bringing problems that are not life-threatening and that are often ignored or minimized in mainstream medical treatment. However, the relationship between complementary and standard medical care is complicated by the fact that three-quarters of those individuals who use alternative services do not tell their primary care physicians that they were obtaining these alternative or complementary services, so their use of them had the potential to undermine or at least complicate their medical care.

These data provide support for the use of the term integrative rather than complementary or alternative. The idea is to integrate the best of other treatment traditions into modern medical care. The NIH now has a National Center for Complementary and Alternative Medicine (NCCAM) that conducts studies and disseminates information on such treatments. Centers for integrative medicine have been opened at a number of prominent academic and proprietary medical centers. The modalities described briefly below have been shown to be helpful in stress management.

Acupuncture

This ancient Chinese technique is primarily employed in the United States for chronic pain, and to a lesser extent for habit problems or substance abuse. Given the interaction between pain and stress in chronic illness, the pain relief obtained through this technique can also reduce secondary stress and anxiety. Needles are inserted in locations thought to mediate pain perception and healing, usually alone, but sometimes with either mild electrical stimulation (electroacupuncture) or the combustion of a herbal preparation (moxibustion). Acupuncture analgesia has been found to be reversed by administration of naloxone, an opiate antagonist, so mediation of its effects via endogenous opiates is possible. Many patients find that they achieve a sense of well-being after acupuncture treatment that provides them with a respite from the stress of chronic illness.

Biofeedback

Biofeedback involves the use of telemetry recording peripheral muscle tension, skin temperature, or skin conductance (reflecting sweating) to inform people about their physiological responses and their ability to modulate them. This approach has been effective in treating tension and migraine headaches, managing stress, and treating psychophysiological disorders

such as Reynaud's disease, which involves vasoconstriction. Training with the equipment is utilized to teach patients how to enhance their ability to manage physiological responses to stress, tension, or other symptoms and thereby feel less secondary anxiety when a stressful situation arises.

Nutritional and Herbal Treatments

There are longstanding traditions of herbal treatments that contain a mixture of generally low-potency and complex combinations of substances that may have specific therapeutic benefit in some cases, or that may be ineffective or even harmful in others. Digitalis, a mainstay in the treatment of congestive heart failure and other cardiac disease, was originally the active component of foxglove, used as a herbal treatment for dropsy. Research supported by NCCAM has shown that omega-3 fatty acids, found in some fish oils, may be helpful in the management of autoimmune inflammatory diseases. Arthritis and other such diseases may be helped by a combination of interventions, including gentle movement such as *tai chi*, a Chinese technique of exercise designed to redirect energy flow in the body, and pain management including hypnosis and biofeedback. However a recent large study by NCCAM found that the herb hypericum, also known as St. John's Wort, did not appear effective in relieving the symptoms of depression, as had been found in previous studies. L-tryptophan, an amino acid precursor of serotonin, has been used in attempt to increase serotonin levels in the brain. Low serotonin has been linked to depression and impulsive behavior, and the most widely used antidepressants, selective serotonin reuptake inhibitors, increase the activity of serotonin in the synapses between neurons in the brain. However, one manufacturer of these dietary supplements produced batches with a small amount of a very harmful contaminant that produced inflammatory muscle pain in many and a number of deaths as well. While their product has been withdrawn from the market, it is an example of how apparently benign dietary supplements can be harmful. The use of some herbs may enhance peoples' sense of control over their disease, independent of specific effects, and thereby at least temporarily alleviate disease-related stress.

Homeopathy

This treatment regimen, developed in Germany and the United States, utilizes serial dilutions of substances thought to impart therapeutic properties in the water or alcohol that may initially mildly provoke and then help the body to heal symptoms of disease. Homeopathy and also other techniques such as

traditional Chinese medicine emphasize a complex assessment of all bodily systems, treating imbalances in these systems and not just focusing on specific diseased parts of the body. Studies conducted through NCCAM and elsewhere have not proven specific effectiveness of homeopathic remedies beyond what might be expected from placebo response.

Hypnosis

There are a variety of well-established and thoroughly studied methods for teaching patients how to increase their control over mental distress and concomitant somatic discomfort. Hypnosis, for example, is a state of aroused, attentive focal concentration accompanied by a reduction in peripheral awareness. It has proven effectiveness in facilitating anxiety control and inducing analgesia. The techniques most often employed involve a combination of physical relaxation and imagery that provides a substitute focus of attention for the painful sensation. Hypnosis can be quickly induced in a matter of seconds, and patients can be taught self-hypnosis to provide ongoing anxiety and pain control. The ability of hypnotizable individuals to dissociate, or separate psychological from somatic response, can be used to maintain physical relaxation even in the face of emotional distress. This can also help patients to restructure their understanding of the situation that is making them anxious, in part because they are approaching it while in an unusually relaxed state. This is an important concept in many complementary treatments for anxiety such as meditation, massage, biofeedback, and hypnosis: the patient may not be able to alter the stressor itself, but can enhance his or her control over his or her psychological and somatic response to the stressor. This can, in turn, enhance the array of options available to the patient for dealing with that stressor, since he or she is more in control of somatic symptoms and less preoccupied with the effect of the stressor.

Self-hypnosis, for example, has been shown to be quite useful in helping medical patients suffering from procedure anxiety. A recent randomized trial employing hypnosis during interventional radiology procedures demonstrated that patients offered training in hypnosis had less pain, fewer procedural interruptions, less cardiovascular instability, and less anxiety while utilizing only 12% as much analgesic medication from a patient-controlled analgesia (PCA) device.

Manipulative Therapies

Approaches such as osteopathy, chiropractic, and therapeutic massage approach symptoms such as pain and limitation of movement, especially involving

musculoskeletal disorders, through careful assessment of anatomical problems and physical manipulation of them. In chronic and severe but difficult-to-treat problems such as lower back pain, such approaches have shown effectiveness equivalent to more invasive surgical treatment in many cases. They may also help to reduce stress related to pain and disability. These treatment approaches are based upon the idea that one way that stress is experienced and can be treated is in the body. Psychological tension can manifest itself in physical tension and misalignment or dysfunction of parts of the body. The goal is to restore more normal structure–function connections in the body. Realignment physical movement is believed to reduce adverse effects of psychological as well physical stress.

Mindfulness-Based Stress Reduction

Similarly, other techniques involving breathing exercises, self-monitoring and regulation, and meditation, several based on adaptations of Buddhist meditation practices, have proven quite effective in stress management in the medical setting. Jon Kabat-Zinn has developed a model that involves teaching patients with pain, anxiety, and other illness-related problems a mindfulness meditation practice designed to help them

1. control their attentional processes
2. induce physical comfort and relaxation
3. maintain a present orientation
4. enhance empathic connection with others

This method helps patients learn to experience more choice in the management of their perceived stress and to reduce anxiety about the future by more richly immersing themselves in the range of their present experiences, both positive and negative. This helps them accept but put into perspective worries about the future by maintaining enjoyment of the present.

Research with this technique has produced promising results. Kabat-Zinn and colleagues demonstrated in a randomized trial that psoriasis patients who listen to an audiotape teaching mindfulness-based stress reduction had significantly more rapid healing of their skin lesions than control patients who listened to music. Thus, mindfulness training may influence the course of disease as well as reducing stress-related anxiety and pain.

Relaxation Training

Other techniques based upon meditative traditions have also been introduced for stress reduction. Benson

and colleagues have popularized an approach that involves brief exercises designed to help patients manage daily stress and have termed the approach the relaxation response. Simple, brief relaxation exercises have been helpful in managing such problems as mild to moderate hypertension and are recommended in such situations prior to or in conjunction with antihypertensive medication treatment.

Conclusion

There is little doubt that Americans are voting with their pocketbooks and their feet for integrative approaches. Recent research has shown that some of these approaches produce specific therapeutic benefits, while others clearly do not. Even if relief of symptoms is a small but real effect, when the big picture is overwhelming, small amounts of mental and/or physical control can go a long way toward reassuring patients that they can more effectively manage the course of their life with disease. Stress is a normal part of life, and a natural if unwelcome part of the course of disease. The extent to which stress produces distress can be modified by a variety of treatments that engage patients as participants in their care. While results vary, these approaches should be viewed as an opportunity rather than a threat, a potentially useful addition to the management of stress in health care.

Introduction

Influence of Stressors on Drug Self-Administration

Factors Influencing Effects of Stressors

Mechanisms of Stress Action

Does Stress Induce a Drug-Prone Phenotype?

Conclusions

Glossary

Dopamine

A neurotransmitter that, with norepinephrine and serotonin, belongs to the class of monoamines. In the central nervous system there are two principal groups of dopaminergic neurons, one in the mesencephalon projecting to a large number of brain structures and the other in the hypothalamus, controlling hormonal function in the hypophysis. Mesencephalic dopaminergic neurons are divided into two major subgroups: (1) The nigrostriatal neurons (A9) that have cell bodies in the substantia nigra-

pars compacta (SNc) and that principally project to the dorsal striatum and the caudate nucleus and (2) the meso-limbic-cortical neurons (A10) with cell bodies in the ventral tegmental area (VTA) and that project to the ventral striatum, nucleus accumbens, and cortical and limbic structures, such as the amygdala and the hippocampus.

Drug self-administration

Intravenous drug self-administration is one of the most used models for studying drug abuse in animals. This test measures the learning of an operant response, such as pressing a lever, which stimulates drug infusion, i.e., this test measures the capacity of pharmacological substances to act as positive reinforcers.

Glucocorticoids

Consisting of cortisol in humans and corticosterone in rodents, this is the final step of the activation of the hypothalamo-pituitary-adrenal axis. These hormones have large effects in the periphery, where they modify energy metabolism and the activity of the immune system. Glucocorticoids also act at the level of the central nervous system. These hormones cross the blood-brain barrier easily and bind to two types of specific intracellular receptors, which are hormone-activated transcription factors. Glucocorticoids also seem to have direct membrane effects, although the mechanism of this action remains unclear.

Negative reinforcer

A stimulus that induces a subject to respond in a manner that interrupts the response. Foot shock is the most common negative reinforcer used in animals. Stressors are usually stimuli that can also act as negative reinforcers.

Positive reinforcer

A stimulus that increases the probability of a response. For example, positive reinforcers are food, a receptive sexual partner, and drugs of abuse.

Introduction

This article analyzes the interactions between stress and the responses to drugs of abuse. In particular, it focuses on intravenous drug self-administration, one of the principal experimental models of drug abuse. Much of our information on the interaction between stress and drugs of abuse is based on experimental studies and in particular from research in rats. Although several authors have proposed that stress is related positively to abuse of both opioid and psychostimulant drugs, a firm causal link between stress and drug abuse cannot be established on the

basis of studies in humans. There are two main reasons for this. First, the variables under investigation, i.e., the history and the experiences of the subject, in humans cannot be manipulated directly under controlled experimental conditions, but only assessed indirectly on the basis of retrospective self-reports of stress. Second, a reliable measure of the outcome of stress on drug abuse implies that all individuals have equal access to drugs under identical environmental conditions. Again, this experimental setting is impossible to achieve in humans. As will be reviewed, this type of experimental investigation has revealed some of the biological factors that mediate stress-induced propensity to self-administer drugs of abuse.

Influence of Stressors on Drug Self-Administration

Definition of Stress

Stress is a very vague concept often used with different meanings that principally refer to a subjective state with a strong negative connotation. Because subjective states cannot be investigated directly in animals, experimental research on stress has focused principally on the behavioral and biological responses to the forced exposure to stimuli or situations that are normally avoided by the individual. This is why stimuli used as experimental stressors are very often identical to aversive stimuli used as negative reinforcers in learning tasks. Consequently, stress, as studied in animals, probably corresponds to "the internal status induced by the exposure to threatening and aversive stimuli." However, what is principally studied in stress research is a panoply of responses induced by aversive stimuli.

Model of Intravenous Drug Self-Administration

The experimental study of drug abuse has been made possible by the discovery that animals self-administer drugs intravenously. This behavior shares many similarities with drug use in humans. First, animals self-administer practically all the drugs that induce addiction in humans. Second, the patterns of self-administration of the different drugs in humans and animals are similar. Finally, the large individual differences in the response to drugs of abuse that characterize humans are also found in animals.

Self-administration measures positive reinforcing effect of drugs, i.e., the learning of an operant response, such as pressing a lever, that has as a consequence the delivery of a drug infusion. In general, changes in the rate of the response reinforced by the

drug are considered to reflect changes in the sensitivity to its addictive properties.

Self-administration is usually studied using three different and complementary approaches: acquisition, retention, and reinstatement. The influence of different forms of stress on the three aspects of self-administration will be analyzed separately.

Influence of Stress on the Acquisition of Self-Administration

Acquisition studies evaluate the propensity of an individual to develop drug self-administration. For this purpose, the effects of first contact with low doses of the drug are studied, and parameters such as threshold or rate of acquisition are taken into account.

In adult animals, artificial and physical stressors, such as repeated tailpinch (Figure 1, top) and electric foot shock, facilitate the acquisition of the self-administration of psychostimulants, such as cocaine and amphetamine. Food restriction is another physical stressor that facilitates the acquisition of psychostimulant, opiate, and alcohol self-administration.

The acquisition of psychostimulant self-administration is also enhanced in male and female rats exposed to an aggressive biological 'congener' and in male rats raised in colonies in which there is a high level of social competition, i.e., colonies in which male rats fight to establish and maintain the social hierarchy that will determine access to females. Facilitation of the acquisition of morphine and alcohol oral self-administration, as well as of heroin intravenous self-administration is also induced by social isolation.

Early life events, such as prenatal stress, also increase the propensity to develop amphetamine self-administration. Such an effect has been observed in adult rats whose mothers had been submitted to a restraint procedure during the third and fourth weeks of gestation.

Influence of Stress on Retention

Retention studies are performed after prolonged training with high doses of drug and allow estimation of changes in (i) the sensitivity to the reinforcing effects of drugs and (ii) the motivation to self-administer drugs. The sensitivity to drugs is assessed by performing dose-response curves. In this case, the dose of the drug per infusion is varied, usually between sessions, and the rate of responding is recorded. Motivation for drugs is evaluated principally by means of progressive ratio schedules. In this case, the dose is maintained constant and the ratio requirement (number of responses necessary to obtain

Figure 1 Examples of the effects of stress on intravenous self-administration. Top: effects of tail pinch on the acquisition of the self-administration of amphetamine ($10\mu\text{g}/\text{infusion}$). Center: effects of food restriction on the dose-response curves of etonitazene self-administration. Bottom: influence of electric foot shock on the reinstatement of heroin self-administration. Stress facilitates the acquisition of self-administration, induces an upward shift of the dose-response function, and triggers the reinstatement of drug-seeking behavior. Redrawn with permission from, respectively, Piazza, P. V., Deminiere, J. M., Le Moal, M., et al. (1990). Stress- and pharmacologically-induced behavioral sensitization increases vulnerability to acquisition of amphetamine self-administration. *Brain Research* **514**, 22–26; Carrol, M. E. and Meich, R. A. (1984). Increased drug-reinforced behavior due to food deprivation. *Advances in Behavioral Pharmacology* **4**, 47–88; and Shaham, Y. and Stewart J. (1995). Stress reinstates heroin-seeking in drug-free animals: an effect mimicking heroin, not withdrawal. *Psychopharmacology* **111**, 334–341.

one infusion) is increased progressively. The highest ratio reached by the subjects (breaking point) is considered an index of its motivation to self-administer drugs.

Changes in dose–response functions for psychostimulant and/or opiate self-administration have been observed after social stress, social isolation, and food restriction (Figure 1, center). In all these cases, the stressors induce an increase in the rate of response over a large range of doses, resulting in a vertical upward shift of the dose–response function. This type of shift in dose–response curves suggests an increase in the reinforcing efficacy of drugs in stressed animals. This idea is confirmed by progressive ratio studies. Thus, over a large range of doses, the breaking point for heroin self-administration has been consistently higher for animals subjected to repeated electric foot shock than for control rats.

A large variability has been observed in the effect of social isolation. Indeed, higher, slightly higher, equal, or lower sensitivities to cocaine have all been described in socially isolated rats as compared to grouped rats. The conditions that were considered as controls could also contribute to such variability. In fact, the rate of self-administration of control animals, and not the one of isolated rats, is what really differentiates some of these reports. Not surprisingly, the effects of social isolation appeared weaker when other conditions that facilitate self-administration, such as priming injections of the drug and pretest periods of food restriction, were used concomitantly.

Influence of Stress on Reinstatement

Reinstatement studies are considered a measure of relapse in drug intake. In this case, the behavior is studied after the extinction of previously acquired self-administration. Extinction is usually obtained by substituting the drug with a vehicle solution. Following extinction, the administration of stimuli known to induce craving for the drug in abstinent human addicts, such as low doses of the drug, will reinstate responses to the stimulus that elicited the infusion of the drug during acquisition. The rate of response to this stimulus is the principal measure of reinstatement.

Stressors increase reinstatement of drug self-administration. In rats in which the response to heroin (Figure 1, bottom) or cocaine has been extinguished by substituting the drug with a saline solution, repetitive electric foot shock induces the reinstatement of response to the drug. Stress-induced reinstatement seems to be a very robust and well-documented phenomenon, and it is of comparable intensity to the one induced by other experimental manipulations known

to induce reinstatement, such as the infusion of low doses of the self-administered drugs.

Factors Influencing Effects of Stressors

Predictability and Intensity

Predictability and intensity seem important variables in mediating the effects of stress on drug self-administration. Unpredictable stressors have higher effects than predictable ones. Furthermore, stressors, especially when acute, need to be of a certain intensity in order to increase self-administration. The relationship between the intensity of the stressor and its outcome on drug seeking is also shown by reinstatement studies. Thus, the rate of reinstatement has been found to be a function of the duration of the shocks. However, in the case of prolonged exposure to stress, the duration of the stress seems less important. Similar facilitatory effects on self-administration have been found for stressors that are continuous and for those that are of short duration and administered repeatedly.

Physical Versus Psychological Threats

Although ‘physical’ stressors involving a noxious stimulus such as electric foot shock and tail pinch increase self-administration, physical aggression per se does not seem to be a necessary condition for mediating stress effects. In fact, pure psychological stress is also able to increase drug self-administration. For example, it has been shown that witnessing another rat receiving foot shocks facilitates the acquisition of cocaine self-administration. Similarly, in social aggression experiments, the facilitation of self-administration is also found when the intruder is always protected by a screen grid and consequently never submitted to physical attacks.

Time Contingencies

Both acute and repeated exposure to stress can increase the propensity to develop drug self-administration. However, acute and chronic stress are influenced differently by temporal contingencies. In the case of acute stressors, a short interval between the stressful event and the exposure to the drug appears to be crucial. In contrast, after a prolonged exposure to stress, the interval between the termination of the stress and the exposure to the drug does not seem to be a relevant variable. In this case a facilitation of drug self-administration has also been found when the stress is terminated weeks before the start of the self-administration session. These observations are important from a pathophysiological point of view.

They indicate that repeated stress can induce long-lasting modifications that result in a drug-prone state that becomes independent from the actual presence of the stressor.

Mechanisms of Stress Action

Different mechanisms could mediate the effects of stress on drug self-administration and much remains to be done on this field of research. We will focus principally on the possibility that stressors sensitize the endogenous system of reward by an action on dopaminergic neurons and glucocorticoid hormones. Mesencephalic dopaminergic neurons, particularly their projection to the nucleus accumbens, are considered one of the principal substrates of drug-reinforcing effects. Glucocorticoid hormones are the final step of the activation of the hypothalamic-pituitary-adrenal axis. The secretion of glucocorticoids by the adrenal gland is considered one of the principal biological adaptations to external aggression.

Clearly, an interaction between glucocorticoids and dopamine should not be considered as the only possible mechanism mediating stress effects, but as the best studied of only one of the likely possibilities. **Figure 2** shows schematically the interactions among stress, glucocorticoids, and dopaminergic neurons.

Sensitization of the Reward System

One of the mechanisms by which stress could modify the sensitivity of an individual to drugs of abuse is by modifying the activity of those neurobiological systems that mediate the addictive properties of drugs.

Role of mesencephalic dopaminergic neurons Mesencephalic dopaminergic neurons seem to be a likely candidate for such a neurobiological system. The role of these neurons in drug abuse has been emphasized in several good reviews. In particular, the release of dopamine in the nucleus accumbens is considered one of the major mechanisms of the addictive properties of drugs. Practically all drugs of abuse increase

Figure 2 Possible pathophysiological mechanisms of the increase in drug self-administration induced by acute and repeated stress. The concentrations of glucocorticoids (large squares) determine the level of dopamine release in the nucleus accumbens (small squares). In basal conditions (basal state), glucocorticoid secretion and dopamine release are low, as is sensitivity to drugs of abuse. Acute stress increases glucocorticoid secretion, which, by enhancing the release of dopamine, results in an increase in the sensitivity to the reinforcing effects of drugs of abuse. However, activation of the negative feedback that controls the secretion of these hormones brings the system back to basal levels within 2 h. The increase in the concentrations of glucocorticoids induced by repeated exposure to stress will progressively result in a long-lasting increase in the secretion of these hormones and in the release of dopamine in the nucleus accumbens. These changes will, in turn, determine a long-lasting increase in the sensitivity to the reinforcing effects of drugs of abuse. The transient increase in glucocorticoids and dopamine observed after acute stress may explain why, in this case, an increase in drug self-administration is found only if the exposure to drugs closely follows the stressor. The long-lasting increase in the activity of these two biological factors could explain why, after repeated stress, an increase in the sensitivity to drugs is also found long (weeks) after the end of the stressor.

dopamine release in this brain area, and an increase or a decrease in dopaminergic activity in the nucleus accumbens corresponds, respectively, to an increase or a decrease in the reinforcing properties of drugs. Several types of acute stress transiently increase dopamine release in the nucleus accumbens. In parallel, repeated stress induces a long-lasting increase in the release of this neurotransmitter, particularly of drug-induced dopamine release.

Role of glucocorticoid hormones Glucocorticoid hormones seem to be the link between environmental experiences and mesencephalic dopaminergic neurons. In basal conditions, the administration of glucocorticoids at levels that are in the stress range can increase dopamine release in the nucleus accumbens, whereas the suppression of glucocorticoid secretion has the opposite effect. During stress, a selective blockade of stress-induced secretion of glucocorticoids reduces dopamine release by around 50%. Finally, the development of the long-lasting sensitization of the dopaminergic response to psychostimulants and opioids induced by stress is suppressed by the blockade of corticosterone secretion.

That glucocorticoids hormones, through their action on dopamine release, could increase the behavioral responses to drugs is supported by a supplementary set of data. First, administration of glucocorticoids, at levels that are in the stress range, increases the propensity to self-administer amphetamine. Second, the blockade of stress-induced corticosterone secretion induces a downward shift in the dose–response curve for cocaine self-administration, i.e., changes opposite to those observed after stress. Third, the blockade of corticosterone secretion can reverse the stress-induced sensitization of the dopaminergic and behavioral responses to cocaine.

Mechanisms of reinstatement The hypothalamic-pituitary-adrenal axis and dopaminergic neurons also seem to play a role in reinstatement, but in a way that differs from the one described for drug self-administration.

For example, a concomitant blockade of D1 and D2 dopaminergic receptors is needed to block stress-induced reinstatement, whereas selective antagonists of either receptor suffice to decrease the positive reinforcing effects of drugs. In parallel, although the injection of glucocorticoids alone can induce reinstatement, blockade of the secretion of these hormones does not prevent the stress-induced reinstatement of heroin self-administration. In contrast, the blockade of glucocorticoid secretion seems to block the stress-induced reinstatement of cocaine self-administration.

Stress-Induced Impulsivity

Changes in impulsivity could be an alternative mechanism by which stress modifies drug self-administration. A deficit in the inhibitory processes that normally operate to control the reward effect of a stimulus is considered an important dimension of impulsivity. This type of impairment could contribute to the increase in drug self-administration induced by stress. This idea is prompted by the effects of social aggression on the rate of responding during time-out periods, i.e., fixed time periods that follow each drug infusion and during which responses are not expected. During time-out, control animals learn quickly to reduce response rates and to wait for the next period of drug availability, whereas stressed rats maintain high rates of response during these time periods. The possibility that an inhibitory deficit is involved in excessive drug consumption is also backed by the finding that the inability to delay gratification predicts alcohol self-administration.

Although stress-induced impulsivity seems an interesting mechanism, further experiments should specifically test the actual occurrence of such a change in behavior. At the neurochemical level it will be important to correlate such potential changes in behaviors with neurobiological modifications involved in impulsivity, such as a decrease in serotonergic activity.

Does Stress Induce a Drug-Prone Phenotype?

The Individual-Centered Vision of Addiction

It is a common observation that although a large number of people take drugs for variable periods of time, only few of them develop a true addiction, i.e., a compulsive drug use that becomes the main goal-directed activity of the subject. One of the theories that has been used to explain such individual differences in the development of addiction postulates the existence of a drug-prone phenotype, i.e., drug abuse is a pre-existing pathological condition revealed by the drug. Addiction would appear only in certain individuals because their biological phenotype will generate a ‘pathological response’ to drugs. This pathological response would make the addictive properties of drugs much greater in some subjects, increasing their likeliness to develop drug abuse.

Knowledge about Drug-Prone Phenotypes

Research in rodents has identified some of the biological factors that could determine a drug-prone

phenotype. As indicated earlier, large individual differences in the propensity to develop drug self-administration have been described in laboratory rats, and the propensity of an individual animal to develop self-administration correlates with its behavior in other experimental situations. For example, animals that show the highest locomotor activity when exposed to a novel environment, a procedure that can be seen as a model of mild stress, also show the highest propensity to self-administer amphetamine.

Animals predisposed to drug addiction show a faster acquisition of drug self-administration, an upward shift of the dose-response function, and reach higher ratio requirements. They also show a higher release of dopamine into the nucleus accumbens in response to a drug challenge and a longer glucocorticoid secretion in response to stress. Finally, the higher dopaminergic activity of animals that are spontaneously drug prone seems to be glucocorticoid dependent. These rats are more sensitive to the dopaminergic effect of glucocorticoids, and blockade of glucocorticoid reduces their dopaminergic hyperactivity.

Stress-Induced Phenotype

Data presented in this article suggest that stressful experiences are one of the determinants of a drug-prone phenotype. Indeed, stressors can induce a long-lasting increase in drug self-administration, and such an effect occur place at an early stage of life, as exemplified by prenatal stress. Further support for this idea arises from the comparison of the characteristics of individuals who are spontaneously drug prone with those of subjects in which such a predisposition has been induced by stress. Indeed, dopaminergic hyperactivity and a dysregulation of glucocorticoid hormone activity, similar to that observed in subjects susceptible to drug addiction, have also been found in individuals made vulnerable by stress.

Conclusions

In conclusion, stress experiences increase the propensity of an individual to develop drug self-administration, inducing a drug-prone phenotype. Stress-induced increases in the secretion of glucocorticoids, which in turn enhance the drug-induced

release of dopamine in the nucleus accumbens, seem to be an important substrate of such an effect of stress.

These observations highlight the importance of environmental experiences in the etiology of drug abuse. This confirms the hypothetical role of stress suggested by correlative studies in humans. Second, the observations support the idea that drug abuse is not simply induced by chronic drug intake, but that the phenotype of the individual plays an important role in determining the development of such a pathological behavior.

Who Experiences Job Insecurity: The Public Health Impact

Summary

Glossary

Downsizing

The most common name given to the process whereby an organization reduces its workforce through natural wastage, early retirement, or redundancy.

Employment security

While job security represents the ability to remain in a particular job, employment security represents the likelihood of being able to remain in paid employment, even if this is a succession of jobs.

Job insecurity

In general terms, the discrepancy between the level of security a person experiences and the level he or she prefers. It can cover both the loss of any valued condition of employment and the threat of total job loss. The depth of the job insecurity experience is dependent on the perceived probability and perceived severity of the job loss. Job insecurity has a large subjective appraisal element that is highly context dependent,

and the job insecurity experience may effect employees who do not lose their job as much as those who do. Job insecurity arising from the threat to a particular job may lead to loss of employment security if subsequent jobs prove hard to find. Job insecurity can be self-reported or externally attributed. The population in studies of self-reported job insecurity is composed of individuals who report their job as insecure. In studies of attributed job insecurity, the study population is deemed to be under threat of job loss by the researchers. Associations observed in studies of attributed job insecurity are likely to be underestimates, as the study population will contain respondents who do not perceive themselves to be under threat.

Primary labor market

The highly regulated section of the labor market in which employees have traditionally enjoyed long-term, secure employment with many benefits, such as occupational pensions, maternity cover, etc.

Psychological contract

Worker's beliefs regarding the terms and conditions of her or his employment. Fairness and good faith are implied in the psychological contract, and breaches have implications for the worker's trust in the organization, performance, and behavior.

Secondary labor market

That section of the labor market in which wages are low and employment rights are few. Such employment is often seasonal, part-time, or temporary and is frequently used to buffer short-term changes in labor requirements.

Sickness presenteeism

Describes the phenomenon that occurs when an employee, despite a level of ill health that should prompt rest and absence, still turns up at work.

Job Insecurity and the Labor Market

Over the past 25 years, large changes have taken place in the structure of the labor market in most industrialized countries. The major determinants of this restructuring have been deindustrialization, technological innovation, globalization, and a commitment to a free market economy, including the privatization of public services. There has been a marked shift from economies driven by manufacturing toward those dominated by employment in services. Technological innovation has allowed many routine functions largely to be replaced by electronic devices (such as cash dispensers), and global information systems have facilitated the rapid transfer of work to newly industrializing countries where labor is cheaper. This deindustrialization and technological change have generally been accompanied by the expansion and strengthening of the role of market forces. Many workers, who previously thought that they had a job for life, now feel much less secure, and job insecurity has become more widespread in all the countries belonging to the Organisation for Economic Co-operation and Development (OECD) since the mid-1980s. Like all social transformations, these changes have the potential to affect the health of individuals and populations.

The Job Insecurity Concept

Research during the major recessions of the 1930s and 1980s provided unequivocal evidence of the adverse effects of unemployment on health, particularly mental health. However, although it is a major determinant of unemployment, much less work has been done on job insecurity. This is partly because job insecurity did not excite attention until it affected white-collar workers in the 1990s and partly because it is less obvious that job insecurity could affect health, as, unlike unemployment, it involves no actual loss of income or status. However, some research has suggested that job insecurity may have detrimental consequences equal to those of job loss. This is consistent with the central proposition in stress research that anticipation of a stressful event provokes as much, if not more, anxiety than the event itself. For workers accustomed to long-term, secure employment, the threat of job loss involves a breach of the psychological contract and generates uncertainty, which, in addition to emotional reactions, can trigger changes in other psychosocial stressors, such as job involvement. The level of stress generated by job insecurity depends on the perceived probability and perceived severity of the threatened job loss. As job insecurity in the primary labor market has increased

and research on psychosocial stressors has gained credence and prominence, interest in the effects of job insecurity has also developed.

Job security is a vital concern for both employees and their organizations. The general concept has been defined by Jean Hartley and colleagues as the discrepancy between the level of job security a person experiences and the level he or she prefers. Job insecurity can also be generated by deteriorating employment conditions and career opportunities, so some investigators have extended the concept to include loss of any valued condition of employment. These definitions encompass large numbers of workers who have insecure jobs, often seasonal, part-time, or temporary. For workers in this secondary labor market, job security is not part of the psychological contract and insecurity is an integral part of their work experience. However, widespread downsizing, privatization, outsourcing, mergers, and closures have led to the suggestion that job insecurity, even for employees in the primary labor market, is no longer a temporary break in an otherwise predictable work life pattern, but is becoming a structural feature of the new labor market. This new employment insecurity brings employees in the primary labor market closer to those in the secondary labor market.

The difficulty in studying the health effects of job insecurity among workers in the secondary labor market is working out whether poor health outcomes can be attributed to job insecurity and unemployment, or whether it is those already in poorer health who are selected into the secondary labor market. For this reason much of the published research has concentrated on workers in the primary labor market.

Job insecurity can be self-reported or externally attributed. Studies of self-reported job insecurity examine workers who say their job is insecure, while studies of attributed job insecurity examine workers deemed to be under threat of job loss because downsizings or workplace closures are expected or are taking place. There is a strong association between self-reported and attributed job insecurity. However, as stress levels are determined by the perceived probability and perceived severity of the job loss, self-reported job insecurity is generally considered to be the more potent stressor.

Mechanisms

Work examining potential explanations of any association between job insecurity and health remains patchy. Studies to date have implicated at least the following: pre-existing ill health; personal characteristics, such as pessimism; material factors, such as financial hardship; non-work psychosocial stressors,

Figure 1 Possible pathways in the association between job insecurity and morbidity. Adapted from Ferrie, J. E., Shipley, M. S., Marmot, M. G., Martikainen, P., Stansfeld, S. and Davey Smith, G. (2001). Job insecurity in white-collar workers: towards an explanation of associations with health. *Journal of Occupational Health and Psychology* 6, 26–42.

such as life events; other psychosocial and physical characteristics of the work environment, such as decreased job involvement; and health-related behavior (Figure 1).

The personal characteristics of pessimism, vigilance, neuroticism, mastery, and self-esteem have been found to explain part of the association between self-reported job insecurity and ill health and health-related outcomes. One of the main explanations of associations between unemployment and health is loss of income. Although job insecurity involves no loss of income, pre-existing deprivation and fear of financial insecurity have been shown to explain part of the association between self-reported job insecurity and self-reported psychological and physical health outcomes. Much has also been made of the potential for job insecurity to interact with other material and psychosocial stressors outside work and to precipitate increases in smoking and drinking.

It seems obvious that organizational change, which involves a reduction in the size of the workforce, in addition to generating job insecurity, is likely to result in changes to other characteristics of the work environment. This has been examined in a number of studies on changes in other psychosocial work characteristics, in particular, loss of job satisfaction, job control, and social support at work. Other work has shown a synergistic adverse effect on health in workers with both high job insecurity and high job strain. Despite this work, much of the association between job insecurity and ill health remains unexplained and

may be due either to direct effects of stress on the autoimmune system or to unobserved health-related selection.

Psychological Health

Most studies that have examined the effects of self-reported job insecurity on health have looked at psychological ill health as an outcome, often as the only outcome. Every study has documented consistent adverse effects on all measures of psychological health, although a combined analysis of the association between job insecurity and mental health outcomes in 37 study samples has estimated the effect size for self-reported psychological ill health to be medium rather than large, with a standardized effect of approximately 25%.

Good evidence for an association between job insecurity and poor psychological health has come from the observation of a dose-response relationship; that is, the higher the level of job insecurity, the greater the increase in psychological ill health. However, a dose-response relationship would be observed whether job insecurity increased psychological ill health or whether ill health increased the likelihood of reporting of job insecurity. In addition, self-reporting of both exposure (job insecurity) and outcome (psychological health) could contaminate the results if some participants have a tendency to report their situation, both work and health, in a negative light. Stronger evidence for the causal precedence of job insecurity

comes from the study of change in job security. For example, it has been shown that, compared to employees whose jobs remain secure, psychological ill health increases among those who report a loss of job security. Studies that follow workers over time also show that self-reported job insecurity acts as a chronic stressor. This means that workers exposed to ongoing job insecurity experience the highest levels of psychological ill health.

Almost all studies of attributed job insecurity have documented an association between insecurity and psychological ill health. Findings from the most notable exception, an early factory closure study in the United States, surprised the investigators. "In the psychological sphere the personal anguish experienced by the men and their families does not seem adequately documented by the statistics" (Cobb, S and Kasl, S. V. (1977). *Termination: the consequences of job loss*. Cincinnati: DHEW-NIOSH Publication no. 77-224, National Institutes for Occupational Safety and Health, p. 180). The observation was attributed to imperfect measurement techniques, as numerous adverse psychological outcomes in individuals were documented in an eloquent narrative account of the closing. Another notable exception comes from a longitudinal study of white-collar civil servants, which took advantage of a natural experiment. In such experiments, a naturally exposed group is compared to an unexposed reference group. This means that there is no plausible selection process involved, and factors such as poor health or age are not influential in increasing the risk of job insecurity. Inferences about causality are strong under such conditions. In this particular natural experiment, well after the initial survey, one of the 20 departments in the study was unexpectedly sold to the private sector, a transfer of business in which most of the workforce lost their jobs. However, no effects on psychological health were seen in either sex in the run-up to the sale. A possible explanation of these seemingly contradictory findings recently emerged from a study that took advantage of a similar natural experiment in the Netherlands. One of the government agencies in the study was threatened with closure after the initial survey. Psychological ill health among employees in this agency was compared with that for employees in agencies unaffected by threat of closure, adjusting for ill health at baseline. Over the 13 months following the closure announcement, the number of new cases of psychological ill health in the closure group was significantly higher than in the nonclosure group. However, the increase in psychological distress among those working in the agency targeted, but who did not think they were at risk of job loss, was not significant; thus, self-reported rather

than self-attributed job insecurity appeared to have been driving the association.

General Measures of Physical Health

Evidence is growing that self-reported job insecurity has adverse effects on self-reported general physical health measures, independent of effects on psychological health, although a combined analysis of the association in 19 study samples estimated the effect size for self-reported general physical health measures to be small, with a standardized effect of approximately 16%.

Reasonably consistent findings have been obtained for a number of health outcomes in both cross-sectional and longitudinal studies. Self-reported job insecurity has been shown to be associated with poor self-rated health, sleep disturbance, chronic insomnia, fatigue, migraine, colds and flu-like symptoms, longstanding illness, and musculoskeletal disorders. Evidence of a dose-response relationship and evidence from studies of change have provided more convincing evidence of a causal association, and there is evidence that self-reported job insecurity acts as a chronic stressor in relation to physical health. The small number of studies that have been able to examine associations between attributed job insecurity and self-reported measures of physical health have observed associations similar to those for self-reported job insecurity. However, there appears to be no evidence that attributed job insecurity acts as a chronic stressor, so it is possible that the finding for self-reported job insecurity may be due to a general tendency for negative reporting.

Very few studies have looked at the effect of either category of job insecurity on biomedical risk factors. There appears to be only two studies that have examined the association between self-reported job insecurity and blood pressure. Both studies found a significant increase in blood pressure compared with control workers who did not report job insecurity. Two studies of attributed job insecurity similarly found significant increases in blood pressure, but another two studies that examined a change in attributed security observed either no significant differences or effects in some groups but not others. Studies that have examined effects on body weight similarly report mixed findings, with no change as well as gain and loss in mean weight being observed. Resolution of these apparently divergent findings may lie in the observation that job insecurity has bidirectional effects on weight. A study of occupational factors and 5-year weight change among Danish men showed that job insecurity increased the likelihood of weight gain among obese men and weight loss among men who were lean.

Apart from two Scandinavian studies, there has been even less interest in biomedical risk factors other than blood pressure and body weight. Attributed job insecurity has been associated with nonsignificant increases in the stress hormone, cortisol, and in cholesterol in a mainly female blue-collar workforce, and levels of adrenal hormones have been shown to be raised among women at the bottom of the white-collar employment hierarchy. However, evidence on cholesterol from a longitudinal study of white-collar civil servants is mixed, and it remains uncertain what clinical relevance the observed changes in biomedical risk factors may have. Hardly any work has examined the effect of job insecurity on diagnosed diseases. Three studies have documented an association between self-reported job insecurity and various measures of coronary heart disease, and an association has been observed between attributed job insecurity and risk of ischemia (abnormal ECG or diagnosed angina) relative to unexposed employees. However, overall the evidence is limited. While the findings were indicative of adverse changes, these were modest and not significant after adjustment for major confounding somatic and behavioral coronary risk factors.

In part because job insecurity was rarely studied until the recession of the 1990s, there has been little research on the effect of job insecurity on mortality from diseases or suicide. Studies of self-reported job insecurity have not been documented, and there is no compelling evidence yet of an association between attributed job insecurity and premature death. Most work prior to the 1990s was a spin-off of studies of unemployment and health and found no significant differences between groups of workers exposed and unexposed to attributed job insecurity. More recently, a factory closure study in New Zealand examined mortality at the end of an 8-year follow-up as an outcome under the conditions of a natural experiment. The study found no statistically significant difference in the death rate for any cause between workers in the closing plant and in the control plant. This was by far the largest factory closure study to date, with nearly 2000 in both the study group and the control group. However, the number of deaths after 8 years was still relatively small, and instability in the sector, which led to the closing of the control plant by the end of the follow-up, may mean that these findings are minimum likely estimates of effects. Although temporary workers are generally considered to be part of the secondary labor market, recent work using Finnish data has looked at the effect on mortality of transfer from temporary to permanent employment. Moving from temporary to permanent employment is associated with a significantly lower risk of death, while remaining in temporary

employment is associated with a significantly higher risk of death than being continuously in permanent employment. While moving the fittest temporary workers into permanent employment is likely to explain part of this effect, change in exposure to job insecurity may also contribute.

Consistent with the evidence of effects on psychological health, a review of eight studies of unemployment and suicide that used longitudinal data for individuals showed that in all but one there was greater job instability and occupational problems among suicides compared to nonsuicides. In the New Zealand factory closure study discussed previously, there was a significant, 2.5-fold increased risk of serious self-harm that led to hospitalization or death from suicide, and out of 46 men who lost their job during a U.S. factory closure, two committed suicide. Although this was 30 times the number expected, the number of people in the study population was too small to draw firm conclusions.

Health Outcomes of Interest to the Organization

A small number of studies have looked at the effect of self-reported job insecurity on safety at work. The main finding from this research is that job insecurity increases workplace injuries and accidents through detrimental effects on employee safety motivation and safety compliance. Both self-reported and attributed job insecurity have been associated with increases in short spells and medically certified spells of sickness absence from all causes, musculoskeletal disorders, and trauma. And a longitudinal study in Finland has shown that downsizing increases sickness absence more among low-income than high-income employees. In contrast to these findings, studies of British civil servants and Finnish workers on fixed-term contracts have shown that in some cases attributed job insecurity is associated with decreases in sickness absence, even when the workforce is known to have a higher level of ill health. This phenomenon is called sickness presenteeism and tends to occur when workers feel that being absent from work may increase their chance of redundancy. Unsurprisingly, sickness presenteeism appears to be more common among workers in the secondary labor market.

Job insecurity has also been widely studied in the organizational and managerial literature as a determinant of a number of outcomes that have adverse consequences for organizations, such as commitment, work effort, and productivity. Findings from the Netherlands have shown that not only is job insecurity a strong determinant of job change, but it is often

the most valuable individuals that are most inclined to seek other job alternatives.

Effects beyond the Individual and the Workplace

A downstream effect of the stress caused by self-reported and attributed job insecurity is an increase in health service use: general practitioner (GP) consultations, hospital referrals, hospital attendance, and use of prescribed medicines, in particular, tranquilizers and antidepressants. However, as for sickness absence, effects can go either way, so there is also evidence that those with high levels of job insecurity may forgo a medical consultation or neglect care of themselves for fear of missing work. An in-depth study of effects on health service use also showed that these effects were not restricted to the workers themselves. GP consultations, hospital referrals, and attendance also increased significantly in the workers' families. Other effects on the family include increases in work-family conflict and tension in the home. Evidence of this spill-over confirms results from studies of both categories of job insecurity that have reported adverse effects on family members, family relationships and the behavior of children.

Who Experiences Job Insecurity: The Public Health Impact

Job insecurity is not evenly distributed throughout the working population. Along with unemployment, it falls more heavily on those with fewer skills, those with less education, and those at a disadvantage in the labor market such as immigrants and the disabled. Several studies have now demonstrated a strong inverse association between job insecurity and socioeconomic position, measured as occupational grade, social class, or education. This means that those at the top of the social hierarchy, however measured, are less likely to experience job insecurity than those at the bottom. Such inverse gradients have been demonstrated in specific occupational groups and in general population samples. There is also evidence that the effect of job insecurity on health is highest among those in the lowest socioeconomic group.

Studies of large companies or government employees – contexts in which most studies on the health effects of job insecurity have been carried out – may underestimate the extent of job insecurity in the general working population. A survey of a large sample of the working population in Taiwan found that job insecurity affected 50% of workers, and a study in Switzerland in 1997 showed that 10% of the working population reported a high level of job insecurity.

These may be two extreme examples, but an OECD study showed that in 1996 experience of job insecurity was very common, with on average 67% of workers unable to agree strongly with the statement “my job is secure.” With the experience of job insecurity being this common, any detrimental effects of job insecurity on health can have major repercussion on the health of the working population as a whole.

Summary

Unequivocal evidence of a causal association between job insecurity and health would require longitudinal studies, with information from a period of secure employment for those subsequently exposed to job insecurity, in addition to a well-matched control group who remained in secure employment. Such prerequisites mean that opportunities for ideal studies are rare. Consequently, although research interest in the health consequences of job insecurity has increased, strong evidence of a causal link between job insecurity and many health outcomes remains limited. Despite this, there is now firm evidence of a causal association between both self-reported and attributed job insecurity and all measures of psychological ill health, and evidence of an association with a number of self-reported physical health outcomes.

Self-reported and attributed job insecurity are associated with adverse changes in most biomedical risk factors that have been examined, but effects are mostly nonsignificant. There is an indication that attributed job insecurity is associated with an increase in heart disease, but no evidence yet of an association between job insecurity and death from diseases or suicide. Job insecurity has been shown to increase workplace injuries and accidents through detrimental effects on employee safety motivation and safety compliance. Most studies show that attributed job insecurity is accompanied by an increase in self-certified and medically certified sickness absence. However, lower rates of sickness absence as well as sickness presenteeism among temporary workers and employees facing imminent threat have also been demonstrated. Both self-reported and attributed job insecurity result in increased use of health services and medications among both those directly affected and their families.

It has been proposed that the effect of job insecurity on health may be mediated via changes in health-related behaviors. However, there is little evidence to support or refute this hypothesis. Although some studies have found the effect of job insecurity on health to be partially explained by other work characteristics such as job satisfaction, social support at work, and job control, much of the association

between job insecurity and ill health remains unexplained and may be due either to direct effects of stress on the autoimmune system or to unobserved health-related selection.

Recent work has demonstrated a synergistic adverse effect on health in workers exposed to both high job insecurity and high job strain. In a context of downsizing and reliance on outsourced labor, perceptions of insecurity are likely to be widespread and, as fewer people do more, occur alongside increasing demands and perceptions of low control. If current trends continue, the number of employees exposed to both job insecurity and job strain will probably increase. Despite its limitations, existing research on the stress of job insecurity has much to contribute to policies that will improve the health of workers and their families and prevent adverse effects on the organizations that employ them.

Introduction

Renal Vascular Resistance (RVR)

Sodium Reabsorption

Does Chronic Stress Cause Hypertension by a Renal Mechanism?

Summary

Glossary

Renal sympathetic nerve activity Net activity (measured in Hz) of renal nerve bundles supplying the kidney.

Renal vascular resistance Vascular resistance of blood flow through the kidney, calculated as systemic mean arterial blood pressure factored by renal blood flow.

Sodium retention Excess reabsorption of Na^+ from various segments of the nephron, resulting in increased extracellular volume.

Introduction

The kidney's primary function is to maintain homeostasis by the efficient elimination of excess fluid and solute. This key function is regulated by both extrarenal and intrarenal mechanisms that control the kidney's ability to maintain proper fluid and electrolyte balance. The sympathetic nervous system (SNS) is an integral part of the homeostatic control system that maintains normal kidney function, with an extensive network of nerves identified in most renal tissues. The SNS modulates short-term regulation of renal function, and under normal conditions renal sympathetic nerve activity is low. During acute stress, however, elevated renal sympathetic activity depresses renal function. Chronic stress studies have been less conclusive and are difficult to design due to additional

pathologies induced by stress, such as hypertension and cardiovascular complications. Major renal effects of mental stress include increased renal vasoconstriction, causing greater renal vascular resistance (RVR), and increased Na^+ transport, causing greater Na^+ retention. Both of these effects may contribute to the development of hypertension, and some investigators propose that this may be the primary mechanism of human essential hypertension. Therefore, most studies on the renal effects of stress have focused on its relationship to hypertension. Though the effects of stress are more pronounced in hypertensive humans and animals, stress increases renal vasoconstriction and Na^+ retention in normal subjects and animals, as well.

Renal Vascular Resistance (RVR)

The systemic blood pressure determines the renal perfusion pressure (RPP) and is a major determinant of RVR. The kidney has a unique ability to autoregulate its own blood flow that is efficient over a wide range of RPPs. Renal blood flow (RBF) changes very little over a large range of RPPs, therefore maintaining a stable RVR. This is due to the exquisite control of vascular tone in the primary renal resistance vessels, the preglomerular afferent arterioles and the postglomerular efferent arterioles. However, many hormonal and neural disturbances can alter autoregulation, often targeting these arterioles, leading to inappropriate increases in RVR. Increased sympathetic activity increases arteriolar resistance and RVR. Increased RVR exacerbates hypertension via its contribution to overall increased total peripheral resistance (since RBF is 20–25% of cardiac output) and its ability to promote Na^+ reabsorption. Stress can induce both neural and hormonal changes that affect RVR.

Renal Sympathetic Nerve Activity (RSNA) and RVR

Multiple studies using several types of acute stress in rats have shown that RBF is reduced and blood

pressure (BP) and RVR over the period of stress are elevated. Renal sympathetic nerve activity (RSNA) when measured is increased and is now associated with the stress-induced changes in RVR. Renal sympathetic nerves act primarily by release of norepinephrine (NE), and nerve endings extend to most renal structures, including arterioles and tubules. In studies designed to test the effects of RSNA alone, higher RSNA frequencies within the range observed during stress increased RVR. The mechanism of RSNA stimulation on vascular tone is linked to increased release of NE and higher circulating epinephrine, acting on α - and β -adrenergic receptors, modulated by Ang II.

Experiments that stimulated RSNA show that there are at least three renal neuroeffector targets: renin-containing juxtaglomerular cells, the tubule, and the arterial vascular resistance. The sequence of RSNA input shows that renin is released at lower levels of RSNA, tubular reabsorption is increased at slightly higher intensities, and renal vasoconstriction occurs at even higher intensities. Each system appears to be regulated differently over a range of RSNA. Nonetheless, it appears that only moderate stress is sufficient to increase RSNA to levels that can alter major renal effectors. The role of RSNA on the renal contribution to hypertension is less clear. In studies in which periodic or prolonged periods of stress increased RSNA, there are only short-term effects on BP.

Many of the RSNA pacing studies have been limited to anesthetized rats, which may have altered basal RSNA. However, recent radiotelemetry techniques developed to measure RSNA in conscious rabbits exposed to stress have confirmed the role of renal nerves on increased RVR and have been used to explore the mechanisms. In response to air jet or white noise stress, RSNA was increased by 55 and 40%, respectively, within 1–2 min, and returned to normal by 9 min in conscious rabbits. Following treatment with rilmenidine, an imidazoline I (1) receptor agonist that reduces sympathetic-induced vascular tone, basal RSNA was reduced. However, the early response to air jet stress was reduced by 35%, whereas rilmenidine had no effect on white noise stress. Therefore, stress stimulates RSNA, but different stressor pathways may involve different central processing.

Increased RSNA impairs renal autoregulation, but the effects appear to be greater in hypertensive animals, suggesting a critical interaction with BP and RPP. However, stress also increases RSNA and BP in normotensive animals. WKY rats exposed to two different strategies of territorial stress (TS) developed higher BP over 5 months compared to control,

unstressed rats. There was no evidence that changes in renal function contributed to the hypertension. Indeed, renal function in spontaneously hypertensive rats (SHR) in which higher BP correlates to RSNA is not different from normotensive WKY. However, in this study TS rats had higher levels of serum corticosterone and catecholamines early in the study, but the values were similar to unstressed rats after 10–12 weeks. This suggested that early exposure to stress might have long-term effects. To test this idea, young normotensive rats were exposed to acute injection of the α -1 adrenoceptor agonist phenylephrine, which transiently increased BP and decreased glomerular filtration rate (GFR). After recovery, the animals were normotensive, but developed hypertension with reduced GFR when exposed to a high-salt (HS) diet, 8–10 weeks later. Together, these studies suggest that stress-induced surges in catecholamines, rather than constant stress, may enhance the susceptibility to other environmental stimuli, such as HS intake, and lead to hypertension and renal injury.

Based on the results from rat denervation studies, chronic increases in RSNA impact renal function. Under normal conditions, RSNA is low and renal denervation does not lead to changes in RBF or RVR. However, when RSNA is high, such as in the SHR or in heart failure rats, renal denervation increases RBF and decreases RVR. This occurs despite the similar RBF measured in intact SHR and WKY rats. Denervation does not alter RBF in WKY. This shows that chronic stress/increased RSNA tends to suppress RBF and increase RVR in SHR. However, it is not clear whether this effect contributes to the development of hypertension in SHR.

The role of stress on RVR has also been studied in human models, where stress-induced renal vasoconstriction also increases RSNA. RSNA is determined by measuring plasma or renal outflow of NE. In healthy volunteers, a short period of mental stress was accompanied by increased renal release of NE and epinephrine (Epi) and renin release, which led to a 48% increase in RVR. Renal arteries also appear to be more sensitive than other visceral vessels to stress in humans. Renal artery (RA) and small mesenteric artery (SMA) resistance and blood velocity were measured by simultaneous pulse and echo Doppler ultrasound flowmetry in 16 young female volunteers for 3 min before and 3 min during a mental stress test. RA vascular resistance was increased and RA blood velocity was decreased during the first minute of stress. SMA resistance was modestly increased, but velocity was unaffected by stress. This suggests that renal blood flow is exquisitely sensitive to mental stress and the accompanying increase in RSNA.

Hormonal Modulators

In addition to direct actions of renal nerves and activation of α -adrenergic receptors, multiple vasoactive hormones may contribute to stress-induced RVR. Endothelin is a peptide hormone that acts on receptors in endothelial cells and on vascular smooth muscle cells, generating vasoconstriction. In a series of human trials in elderly and young women, acute mental stress (30 min) increased BP, heart rate (HR), plasma NE, effective renal plasma flow, and RVR, but its effect on RVR was more prolonged in the elderly group. Urinary excretion of endothelin-1 was elevated in both groups, whereas excretion of vasodilating prostaglandins and nitric oxide (NO) was high only during the mental stress period in elderly subjects but was sustained at a higher excretion levels in young subjects. The balance between these opposing vasoactive hormones may therefore determine the level of stress-induced RVR. These studies provide good evidence that the balance between renal vasoconstrictors and vasodilators is invoked in the kidney's ability to autoregulate blood flow during mental stress. However, studies that evaluate the direct effects of endothelin infusion do not support a major role for endothelin as a potent vasoconstrictor during stress.

Several studies have shown that renin is released into the renal circulation during various forms of stress. However, it is not clear whether the levels of renin and locally produced Ang II are sufficient to contribute to the increased vasoconstriction that accompanies increased sympathetic activity. One report suggests that Ang II modulates the effects of catecholamine activation of adrenergic receptors, but the interaction has not been carefully investigated.

The role of NO was examined in adult borderline hypertensive rats (offspring of SHR and Wistar rats) during 5 weeks of crowding stress. Compared to unstressed controls, BP, HR, and nitric oxide synthase (NOS) activity in the aorta were higher. However, NOS activity in the heart, adrenal gland, and kidney was not affected. Superoxide (O_2^-), which scavenges NO, may contribute to RSNA. The higher RSNA activity in SHR compared to WKY was normalized by tempol, a powerful antioxidant, which reduced BP and RSNA to a greater extent in SHR than in WKY. However, the effect of reactive oxygen species on other influences on renal function could not be ruled out in this study.

The renal levels of neuropeptide Y (NPY) and calcitonin gene-related peptide (CGRP) were measured following a period of mental stress (word conflict test) or after low-dose adrenalin infusion in 12 healthy volunteers. Mental stress caused a threefold

increase in NE renal overflow but had no effect on NPY or CGRP, whereas Epi infusion increased levels of all neurotransmitters.

The pro-inflammatory transcription factor nuclear factor- κ B (NF- κ B) has been linked to psychosocial stress as a possible mediator of organ damage, specifically in the kidney. NF- κ B activation in renal tissue was greater in tissue from patients with renal complications. NF- κ B in peripheral blood mononuclear cells (PBMC), which can be easily measured, correlated with the degree of albuminuria in diabetic nephropathy patients and was reduced by antioxidant therapy. Similar levels of NF- κ B activation in PBMC were observed in healthy volunteers during a 15-min psychosocial stress test. The activation of NF- κ B in PBMC correlated with the stress-induced increases in catecholamines and cortisol. Though the long-term effects of stress on NF- κ B have not been tested, these acute studies provide a possible mechanism of kidney damage caused by stress.

Sodium Reabsorption

A major hypothesis for the development of hypertension invokes the role of the kidney in the inappropriate retention of solute and fluid resulting in increased fluid volume. In order to maintain homeostatic control of body fluids during periods of hypertension, the kidney excretes greater levels of urine and solute, resetting a lower extracellular fluid volume. However, the increases in BP seen during periodic stress does not always generate this pressure-natriuresis response, partially due to the increased RSNA, which simultaneously increases Na^+ reabsorption. As some studies suggest, the inability to excrete more solute and fluid during periods of increased BP may predispose those individuals to hypertension. The observation that acute stress can cause Na^+ retention has led to the popular theory that human essential hypertension is primarily due to chronic stress mediating excess extracellular fluid volume via a renal mechanism. Acute stress clearly increases RSNA, and several animal models of hypertension show increased renal sympathetic activity. However, RSNA is determined by postganglionic fibers and is controlled by the arterial baroreceptor reflex, which is not associated with long-term BP control. Though recent evidence shows a stronger correlation of RSNA and long-term control, RSNA generated by stress provides primarily acute regulation of renal function-induced hypertension.

Animal studies show that acute stress consistently increases RSNA and decreases Na^+ excretion in normotensive rats and dogs and does so to an even

greater extent in hypertensive rats. The neurohormonal regulation of these effects has been the focus of several studies. In conscious rats, a 10-min air jet stress increased BP and RSNA and reduced urine volume and Na^+ excretion by three- to fourfold (Figure 2). After denervation, urine volume and Na^+ excretion were not affected by stress, demonstrating the dependency of neural activity. Treatment with an AT1-R antagonist also prevented a decrease in urine flow or Na^+ excretion after stress, though RSNA was not affected. This suggests that Ang II mediates the antidiuresis and antinatriuresis induced by stress without affecting nerve activity. Previous studies showed that increases in RSNA led to greater Na^+ reabsorption, which was mediated by α -2 receptors. Inhibition of Ang II also decreased the RSNA effect, suggesting that Ang II interacts with α -2 receptors to regulate Na^+ reabsorption. Therefore, changes in RSNA induced by mental stress may have similar regulation by Ang II and α -2 receptors.

Results from human studies are less consistent but do show the effects of stress, and the associated increases in sympathetic activity on Na^+ retention are more closely associated with hypertension than in normotensive humans. In a well-controlled human subject trial, two 20-min periods of stress increased BP and decreased Na^+ excretion in 10 normotensive adult males, without altering GFR, measured by the clearance of inulin, or renal plasma flow (RPF), measured by the clearance of para-aminohippurate (PAH). Fractional Na^+ reabsorption was increased by stress and was primarily due to increases in reabsorption in the proximal tubule (PT), based on fractional lithium clearance measurements. Rilminedine, an imidazoline-I1 receptor antagonist, lowered basal BP but did not alter the effects of stress.

In a study that tested the interaction of hypertension and stress on renal function, three groups were evaluated: normotensive offspring of hypertensives (HP), hypertensive subjects (HT), and normotensive offspring of normotensives (NP). Basal BP, which differed between groups, was elevated by stress in all groups. However, the BP increased more in HP than in the other groups (Figure 1). Basal GFR and RBF were higher in HP than in the other groups. However, GFR was reduced by stress in HP and HT but not in NP, and RBF was reduced in HT and NP but not in HP. More interesting, however, were the responses to stress in normal subjects. Stress increased the filtration fraction, which suggests that efferent arteriolar resistance was elevated. There was also a paradoxical decrease in Na^+ excretion given that BP was higher. Again, the decrease in Na^+ reabsorption was attributed to increased PT reabsorption, based on the changes in lithium clearance.

Figure 1 The effect of stress on GFR, RPF, and filtration fraction (FF) in normotensive (NP), normotensive with hypertensive parents (HP), and hypertensive (HT) subjects. From Ducher, M., et al. (2002). *American Journal of Hypertension* 15, 346–350. © 2002 American Journal of Hypertension, Ltd.

However, Na^+ retention induced by stress is not always observed in normal subjects. In three groups designed to test the potential for the development of hypertension, the effects of mental stress on Na^+ excretion were evaluated in normotensive young males with and without a family of hypertension and compared to hypertensive males. Each subject was studied with or without 1 week of therapy with an angiotensin converting enzyme inhibitor (cilazapril). A 30-min period of mental stress led to increased BP, HR, and GFR and decreased RBF in all groups. However, Na^+ excretion was increased in both normotensive groups, eliciting the appropriate pressure-natriuresis response, whereas the hypertensive group failed to change. Angiotensin converting enzyme therapy restored the increased Na^+ excretion in the hypertensive group, suggesting that the failed natriuretic response is due to the observed elevation of Ang II in hypertensive subjects. Together, these studies suggest that individuals who respond to stress by decreasing

Figure 2 Effects of 10-min air-jet stress on BP, HR, urine flow rate (UV), and Na^+ excretion rate (U_{NaV}). UV and U_{NaV} are reduced during stress in conscious control rats. This effect is blocked by either denervation (DNX) or by Ang II, type 1 receptor blocker (ZD7155). From Veelken, R., et al. (1996). *Hypertension* 28, 825–832.

Na^+ excretion are predisposed to Na^+ retention and hypertension, whereas normotensive humans with the appropriate natriuresis response to stress are less likely to progress to hypertension via stress.

Does Chronic Stress Cause Hypertension by a Renal Mechanism?

As discussed previously, most of the studies that have shown increased RSNA, RVR, and Na^+ reabsorption to stress were observed during acute stress. Under these acute conditions the increased RVR and renin release may contribute to the acute rise in BP. However, it is difficult to assign a role for Na^+ retention in

acute hypertension, which occurs almost immediately. Therefore, caution should be observed when using acute studies to interpret chronic stress-induced hypertension. Studies in normotensive rats and mice have shown that prolonged stress for as much as 4–5 months increases BP during this period. Mice have shown progressive arteriosclerosis, myocardial hypertrophy, increased catecholamine levels, and greater angiotensin sensitivity, since Ang II blockade prevented hypertension. However, there were no measurements of Na^+ balance during the development of hypertension to evaluate the kidney's role. In hypertensive models, such as SHR, renal function and volume status also rarely differ. The use of prehypertensive models

has suggested a stronger role for the kidney in the development of hypertension but has not controlled adequately for the genetic backgrounds of these models. A more valuable set of data has been made in renal denervation studies, which have indicated that antinatriuresis and renal vasoconstriction may be due to the elevated RSNA in SHR.

Another issue of concern is that stress in rodents and humans may differ substantially. Human studies have not always found renal dysfunction in acute stress in normal subjects. This would be expected, since genetic predisposition appears to be necessary for the failure of the kidneys to adjust to high BP with appropriate natriuresis. It is possible that some normotensive subjects used in these studies had unknown genetic predisposition. Rodent studies have consistently shown the lack of renal compensation to acute stress, which is surprising but may not relate to the kidney's role, if any, in chronic stress. Indeed, chronic stress in rodents has been associated with cardiac and vascular remodeling.

The proper resolution of this question, at least in animals, will require a reproducible chronic stress model in rodents with noninvasive measurements of BP and renal function that can measure the critical components of renal influences on the development of hypertension over a chronic period. Lacking this type of information, the current evidence does not strongly support a role for changes in renal function contributing significantly to chronic stress-induced hypertension.

Summary

In summary, acute mental stress increases RSNA, BP, RVR, and Na^+ reabsorption in both animal and human studies. These effects are exaggerated in borderline hypertensive or hypertensive subjects, and many effects are blocked by Ang II inhibition, though multiple hormonal systems may be involved. The effects of chronic mental stress are more controversial, with few consistent observations. Though RSNA and general sympathetic activity is increased

in SHR, there are rarely any reports of renal dysfunction that would be expected if stress had permanent effects on renal function. The concept of mental stress altering renal function that leads to hypertension needs further experimental evidence.

Critical Issues in Korean Conflict Trauma Research

Combat Exposure

Lasting Effects of Combat Exposure

Summary

Prior to the Korean conflict (1950–1953), combat-related posttraumatic stress reactions, variously termed battle fatigue, war neurosis, and combat exhaustion, were considered a temporary condition best treated close to the combat zone. Influential theoretical perspectives included Freudian concepts of defense mechanisms as adaptations to stress-induced intrapsychic conflicts and, later, Selye's general adaptation syndrome, stress reactions viewed as a three-stage physiological response. Psychiatry during World War II and the Korean conflict viewed traumatic war neurosis as a complex phenomenon resulting from "multiple physical and psychic forces struggling for emotional control . . . the stimuli of battle itself evoked a defensive process that sustained men in combat . . . the lonely, fearful battle environment forces individuals to join together for protection and emotional support" (Glass, 1954: 728). The military unit was seen as a key source of support and motivation for soldiers to return to active combat. Therefore, all but the most severe cases of psychiatric casualties were treated at the front lines.

Further reinforcing the belief that combat-related posttraumatic stress reactions were short-lived, the publication of the first edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-I) in 1952 established responses to either combat or civilian catastrophe invoking overwhelming fear, "gross stress reaction," as a temporary condition. Any protracted course of symptoms was attributed to an unrelated neurosis. Subsequently, the 1968 edition, DSM-II, dropped "gross stress reaction," relegating combat-related posttraumatic stress reactions to an adult adjustment problem.

Critical Issues in Korean Conflict Trauma Research

Nevertheless, the most prevalent service-connected disability in a sample of former Korean prisoners of war (POWs) was anxiety neurosis (19.2%). Few researchers at the time examined the psychological impact of combat-related traumatic stress on Korean veterans. In fact, most clinical and empirical research on the possible long-term psychological sequelae of the Korean conflict did not begin in earnest until the 1980s, three decades later, and only after a substantial amount of research had been conducted on posttraumatic stress disorder (PTSD) among Vietnam veterans. These retrospective studies all suffer from sampling problems that make it difficult to generalize from their findings to all Korean conflict veterans. Some studies did not differentiate Korean veterans from World War II veterans, whereas all the remaining studies focused exclusively on treatment-seeking veterans or POWs, each a highly select group.

Combat Exposure

Despite limited data, certain trends can be seen. It is clear that some Korean combat veterans were exposed to high levels of war-zone stress. Indeed, Blake and colleagues found no significant differences for combat exposure or posttraumatic stress symptomatology between Korean combat veterans and either World War II or Vietnam combat veterans. In an early study, Korean veterans reported that their combat-related posttraumatic stress symptoms not only persisted but actually worsened over time.

One of the best-studied groups of Korean combat veterans are former POWs. Like non-POW Korean combat veterans, Korean POWs reported that they had continued to experience posttraumatic stress symptoms years, even decades, after the trauma. Consistent with studies demonstrating a dose-response relationship between traumatic exposure and posttraumatic stress symptoms, Korean POWs reported higher levels of posttraumatic symptoms than non-POW Korean combat veterans. Whereas Korean POWs experienced less combat exposure than non-POW Korean veterans, the combat they had experienced before their capture was fierce with heavy casualties. After capture, they were sent on death marches and were subjected to brainwashing techniques and long periods of physical deprivation, interrogation, and solitary confinement. Thirty-eight percent of Korean POWs died during captivity.

Lasting Effects of Combat Exposure

Despite the circumscribed number of empirical investigations, the existing database suggests that, in addition to PTSD, Korean POWs and combat veterans have experienced long-term consequences of traumatic exposure, including alcohol abuse, depression, and general psychiatric distress. Further, higher mortality rates, especially due to accidents, appear to occur among Korean POWs than are expected for U.S. males. With respect to their World War II counterparts, Korean veterans had a higher lifetime prevalence of suicide attempts, more frequent occurrences of drug abuse-related hospitalizations and outpatient treatment, and greater use of mental health outpatient treatment. However, fewer Korean veterans met diagnostic criteria for PTSD. Nevertheless, Korean POWs reported higher rates of posttraumatic stress symptomatology and depression than World War II POWs.

Compared to Vietnam counterparts, Korean veterans reported lower levels of alcohol or drug abuse and fewer occurrences of drug abuse-related hospitalizations and outpatient treatment. Korean veterans were more likely than Vietnam veterans to recognize, early in their disorder, the link between their symptoms and their combat exposure. However, less use of PTSD treatment programs was found among Korean veterans.

Summary

Relative to Vietnam and World War II veterans, few researchers have included Korean veterans in their studies. A caveat should be exercised when drawing conclusions from studies of highly selective samples of war-era groups that differ in important areas such as age, premilitary socioeconomic status, time since combat exposure, POW status, repatriation, and social attitudes. Nevertheless, it seems apparent that traumatized Korean veterans suffer chronic debilitating posttraumatic psychological consequences of their war-zone experiences.

Original Observations and Theory
Learned Helplessness and Psychopathology in Humans

Glossary

<i>Explanatory style</i>	A person's characteristic ways of explaining the causes of the events that happen in his or her life.
<i>Shuttle box</i>	Experimental apparatus for animals with two compartments separated by a barrier that can be adjusted by the experimenter.
<i>Uncontrollable reinforcer</i>	A reinforcer whose probability is the same whether an emitted response is present or absent. In this situation, the responding organism cannot control the reinforcer.

Original Observations and Theory

Learned helplessness refers to the motivational, cognitive, and emotional deficits that may follow from an organism's exposure to uncontrollable stressors. The theory arose from the observation that, after experiencing inescapable shock over which they had no control, dogs in the laboratory displayed a variety of behavioral deficits. In the original experiments on the learned helplessness phenomenon, the following

design was typically used. The dogs were first given unpredictable and inescapable electric shocks in a Pavlovian hammock. Then, 24 h later, the dogs were placed in an experimental shuttle box. In this shuttle box, there were two compartments, and the dog was given 10 trials of escape/avoidance training. Shock was given in both compartments, but the termination of the shock took place when the dog jumped from one compartment to the other.

Approximately two-thirds of the dogs placed in the shuttle box after experiencing inescapable shock did not learn the escape/avoidance behavior; that is, they never learned that they could end the shock simply by jumping to the other compartment. Instead, they struggled at first and then stopped attempting to take action that might terminate the shock. The vast majority of dogs who had not experienced inescapable shock prior to entering the shuttle box had no trouble learning the escape/avoidance procedure to terminate the shock. The deficit in many of the previously shocked dogs was psychological rather than physical because these same dogs were able to run out of the shuttle box when the exit was opened.

This learned helplessness effect observed in the previously shocked dogs (i.e., they passively accepted later shock and did not learn to avoid it) was caused by the uncontrollability of the shocks experienced in the Pavlovian hammock. This was demonstrated by Seligman and Maier in 1967 using a yoked experimental design with three groups of dogs. The first group could press a panel in the hammock to terminate the shock. The second group received the same duration of shock as the first group, but could not control the onset or termination of its shock in the hammock. The third group received no shock prior to being placed in the shuttle box. The yoked group,

which had received uncontrollable shock in the hammock, showed the strongest deficits in learning in the shuttle box. The dogs that had received the same amount of shock but could press to control the termination of the shock did not show these deficits.

The deficits observed in helpless dogs fall into three categories. First, motivational deficits exist because the dogs stop initiating voluntary behaviors, such as jumping from one compartment to the other. Cognitive deficits also appear in that the dogs do not learn that their responses have been effective even when they have indeed caused the desired effect. Finally, the dogs show transient helplessness effects that dissipate over time, suggesting that helplessness may be a passing emotional response. Interestingly, exposure to controllable shock in the shuttle box prior to experiencing uncontrollable shocks appears to immunize dogs against later helplessness deficits and forcibly exposing dogs to the appropriate response contingency (i.e., that jumping to the other compartment terminates the shock) can eliminate these deficits.

According to the researchers, the dogs who received uncontrollable, inescapable shock learned that outcomes were independent of their responses. When organisms experience uncontrollable outcomes, they may notice this contingency and learn that the outcomes are independent. They will then expect outcomes to be independent of their responses in the future. This expectation involves a cognitive representation of the contingency. The purpose of voluntary action is to cause certain outcomes, so a belief in response–outcome independence will reduce the organism’s motivation to engage in voluntary responses. Because forming this expectation of independence is an act of learning, this cognitive representation will interfere proactively with future attempts to learn about response–outcome dependence. Finally, the fear that follows a traumatic event may be replaced with negative emotions when the organism realizes its lack of control in the situation. Thus, learned helplessness theory seeks to explain the three primary deficits observed through a cognitive pathway. In their 1976 review paper, Maier and Seligman reviewed alternative hypotheses for the observed deficits and argued that the helplessness account fits most parsimoniously with the available data.

Learned helplessness is not specific only to dogs in the shuttle box. Deficits have also been documented in cats, rats, and humans. These extensions of learned helplessness to animals other than dogs have been empirically and theoretically useful. One study found that helpless rats were less likely to reject cancerous tumors than nonhelpless rats, suggesting an important connection between helplessness and immune function. In humans, several studies used a yoked

paradigm in which participants (college students) in the first group could turn off a loud noise by pressing a button. Students in the second group heard the same noise for the same duration of time as those in the first group, but the sound was not contingent on their pressing a button. A final control group did not hear any noise. In one study conducted by Hiroto, students then put their hand in a shuttle box; they were shocked but could escape by moving their hand to the other side. Just as in the dogs, the students in the uncontrollable group showed helplessness deficits; they did not learn the avoidance strategy and just took the shock. In another study by Miller and Seligman, students who heard the uncontrollable inescapable noise had more trouble solving difficult anagrams than did those who heard escapable noise and those who heard no noise at all.

Learned Helplessness and Psychopathology in Humans

Although these experiments demonstrate that learned helplessness deficits can be produced in humans, a large amount of research has investigated whether the learned helplessness model can be thought of as an analog for various psychological disorders in humans. The most work has been done on depression and posttraumatic stress disorder (PTSD), so we consider here how learned helplessness might be useful for the understanding and treatment of these two types of psychopathology. Although our focus in the remainder of this article is on links between learned helplessness and mental health, there is an additional, smaller body of work linking learned helplessness and physical health in humans.

Depression

In his 1975 book *Helplessness*, Seligman asserted that the learned helplessness phenomenon appeared to be very much like human depression. Specifically, the motivational, cognitive, and emotional deficits that appeared in helpless dogs seemed to mimic the symptoms of reactive depression, in which a human gets depressed after a major life stressor. Certainly the apparent emotional withdrawal and passivity shown by helpless dogs and college students paralleled depression; in addition, decreased motivation and increased cognitive difficulty, also parts of the helplessness experience, are major symptoms of depression. Based on these and other similarities, Seligman hypothesized that both learned helplessness and reactive depressions result from the expectancy that responses and outcomes are independent. Thus, gaining a sense of control would serve as an important part of treatment for depression.

Although the expectancy of future response–outcome independence served as a helpful stimulant for research on the cognitive predictors of depression in humans, there were several flaws with this original learned helplessness conceptualization of depression. First, just as not every dog became helpless after uncontrollable shock, not every human becomes depressed after experiencing stressful events with uncontrollable outcomes. Second, the theory could not distinguish between a depressed person feeling that he or she personally could not effect outcomes and the feeling that the response–outcome independence was true universally.

Abramson, Seligman, and Teasdale therefore offered a reformulated learned helplessness model of depression in their 1978 paper. This cognitively oriented reformulation centered on the notion that, when a life stressor takes place, people do not simply notice the contingencies involved. Rather, they ask themselves why the event happened. People tend to have usual ways of answering this question, and this is called their explanatory style. Causes for events generated by people tend to fall along three separate dimensions: (1) people may feel the cause is due to themselves or to other people or luck, (2) they will either attribute the cause to factors that are stable in time or temporary, and (3) the cause may affect many life domains or just the ones involved most specifically with the stressor. The theory follows a diathesis-stress model of depression onset – it claims that people who have a pessimistic explanatory style, in which negative events are explained with internal, stable, and global causes, will be especially vulnerable to depression when faced with uncontrollable life stressors.

There has been a large amount of empirical support for this model, using both questionnaires (primarily the Attributional Style Questionnaire) and content analysis of verbatim data and a wide range of experimental methodologies. A usual study followed a population prospectively over time to determine whether pessimists were more likely to get depressed after experiencing negative life events. In one series of studies, pessimistic college students experienced the most enduring depressive symptoms after doing poorly on a midterm. A meta-analysis supported the conclusion that a pessimistic explanatory style relates to depression, especially with regard to explanations for negative events. However, the vast majority of studies used either college students or adult psychiatric patients; there is some indication that the relationship between pessimism and depression may be slightly different in older adults. Nonetheless, prevention programs based on teaching pessimistic children and college students to dispute their automatic pessimistic thoughts and to become more realistically

optimistic have produced lower rates of significant depressive symptoms in participants at high risk for depression. In addition, there is some evidence that successful cognitive-behavioral psychotherapy can cause a shift in explanatory style such that clients become more optimistic.

Post Traumatic Stress Disorder

Despite the reformulated learned helplessness model's prominence in research on cognitive approaches to human depression, it is the original learned helplessness model that has primarily (although not exclusively) influenced research on PTSD in humans. The behaviors that follow inescapable shock in animals appear to mimic many of the symptoms of PTSD in humans. As already noted, animals exposed to inescapable shock show cognitive, motivational, and emotional deficits. Similarly, humans exposed to traumatic stressors may show a variety of sequelae, including anxiety and hyperreactivity, isolation, and anhedonia, that are similar to the sequelae observed in helpless animals. After inescapable shock, animals experience a depletion of catecholamine in their central nervous system. Van der Kolk and his colleagues posit that catecholamine depletion, especially norepinephrine (NE) depletion, is also involved in the negative symptomatology of PTSD, such as lack of motivation. They also posit that an augmentation of locus coeruleus pathways causes intrusive PTSD symptoms, such as nightmares and flashbacks.

More important to van der Kolk and his colleagues' work is the analgesia response observed in helpless animals, such that they do not appear to experience pain in response to subsequent stressors presented within a short period of time after the administration of inescapable shock. This response is due to endogenous opioids in the body. Interestingly, there are many parallels between the symptoms of opiate withdrawal and PTSD, leading van der Kolk and colleagues (1985: 320) to hypothesize that "both are, at least in part, due to central noradrenergic hyperactivity associated with a relative decrease in brain opioid receptor binding." This hypothesis is supported by evidence that trauma survivors often put themselves in situations similar to the traumatic event, perhaps in an attempt to evoke endogenous opioid release and thus a sense of calm and control. However, this sense of calm is followed by symptoms of opiate withdrawal, such as hyperreactivity, thus immersing PTSD sufferers in a cycle of reexposure and withdrawal.

Other research on helpless animals finds that the NE depletion may be the outcome of a more immediate increase in NE when a helpless animal is exposed to a mild stressor. The hippocampus of the helpless

animal appears to be conditioned by the inescapable, helplessness-inducing trauma to respond with increased NE to later lesser stressors. This increase in NE secretion immediately after later stressors could be part of the same general catecholamine dysregulation following traumatic stress as the NE depletion reported by van der Kolk.

In addition to the neurochemical and behavioral evidence for a learned helplessness approach to PTSD based on uncontrollable stress, evidence also exists supporting a relationship between helpless explanatory style and PTSD symptoms. McCormick and colleagues studied explanatory style among patients addicted to alcohol and/or gambling and found that patients with PTSD had a more pessimistic explanatory style than those who did not have PTSD. Although correlational, these results suggest that the cognitive reformulation of learned helplessness may also contribute to an understanding of the phenomenology of and potential treatments for PTSD. Moreover, recent work suggests that learning experiences can immunize animals against becoming helpless in the face of stress and that posttrauma therapeutic interventions centered on learning to predict and control stressors can be helpful in the treatment of PTSD in humans. This work suggests that the learned helplessness framework may be useful for both prevention and treatment of stress-related psychological disorders.

Possible Mechanisms of the Relation between Stress
and Memory

Summary

Glossary

<i>Stressor</i>	Stimuli that puts an extra demand on the organism.
<i>Stress hormones</i>	Hormones of the adrenal glands that serve to maintain bodily homeostasis in response to challenging external and emotional environment. These hormones are the glucocorticoids and epinephrine.
<i>Corticosterone</i>	A steroid hormone in many species including rodents produced by the adrenal cortex and involved in response to stress and immune reaction.
<i>Cortisol</i>	A steroid hormone in humans produced by adrenal cortex, involved in response to stress and has direct influence on the nervous system.
<i>Hippocampus</i>	A region of the cerebral cortex lying in the basal medial part of the temporal lobe thought to be important for learning and memory.
<i>Amygdala</i>	A group of nuclei involved in the medial anterior part of the temporal lobe regulating emotion and certain types of learning.
<i>Emotion</i>	Mental state of arousal.

Memory

Encoding of information, storage and recall.

Learning

A relatively permanent change in cognition as a consequence of the acquisition of new information and experience, directly influencing behaviour.

Introduction

Conceptually, the term stress describes a load on the organism. A stressful situation puts extra demands upon the system for cognitive or physical productivity. A stressor, which might be external or internal, can be anything that puts extra demands upon the system, such as a specific problem, issue, challenge, or personal conflict. A stress reaction is the individual's response to a given stressor on the physiological, cognitive, and/or emotional plane. Strain occurs when the organism is overloaded, exposed to prolonged stress, or placed in situations that the system can not cope with. The psychological consequence of strain is fatigue or exhaustion. Traumatic, salient memories that the individual would like to forget but can not may result in a neurotic fixation on the memories of the trauma, i.e., posttraumatic stress disorder (PTSD).

Physiologically, stress might be defined as a state of physiological and emotional arousal of the organism. It leads to the activation of the autonomic nervous system and the hypothalamic-pituitary-adrenal axis. The main signaling hormones of these systems are (nor)adrenaline, corticotropin-releasing hormone, and cortisol (corticosterone in most rodents).

It is generally accepted that stress affects learning and memory processes and that stress might improve as well as impair the acquirement of information. How is this possible? One answer to this question is that there are at least three types of stressors, physical, cognitive, and emotional, which affect different regions of the brain. Another answer lies in the progress that has been made in the knowledge of the effects of stress on the different stages of learning and memory processing.

Although the mnemonic system in animals is considerably more restricted than that in humans, much complementary knowledge about the effects of stress on learning and memory in humans has been gained through animal studies. The following section gives an account of some of the basic research about this topic in animals.

Effects of Stress on Learning and Memory in Animals

Animals learn about the relationship or association between two events. In classical conditioning, the animal learns to associate a stimulus such as a tone (conditioned stimulus) with food (unconditioned stimulus). In operant or instrumental conditioning, the animal learns to associate a response, for instance, pressing a lever (instrumental response), with food reward (reinforcement). It has been suggested by some researchers (e.g., Anthony Dickinson) that associative learning mechanisms have been shaped by evolution to enable animals to detect and store information about real causal relationships in their environment.

Stress Hormones and Learning

The impact of stress hormones in modulating associative learning and cognitive function in animals has been a subject of continued investigation. The studies that have documented the relationship of levels of the stress hormones with cognitive function, such as attention, perception, and memory, have been done mostly in rodents, in which investigators have examined the influence of stress hormones on acquisition, consolidation, and retrieval of information. Glucocorticoids are the stress hormones secreted by the adrenal glands in animals. In primates and dogs, the naturally occurring glucocorticoid is cortisol, whereas in rodents and birds it is corticosterone.

Fluctuations in corticosterone levels can be said to reflect emotional states related to stress. In experimental animals, changes in hormonal levels can be achieved by pharmacological means or environmental manipulations and their effects assessed. Several studies have shown that stress and glucocorticoids influence cognitive function.

The administration of low levels of corticosterone improves performance in learning tasks in animals. However, whereas short-term exposure to low levels of corticosterone can enhance cognitive function, it is known that short-term exposure to higher levels as well as long-term effects of high levels of corticosterone (e.g., through sustained exposure to restraint stress) have deleterious effects on learning, memory, and cognitive function. The biphasic effects of corticosterone on memory formation have been demonstrated in behavioral studies performed in chicks and rats.

Young chicks have a tendency to peck spontaneously at small salient objects in the environment. This natural behavior of chicks has been exploited to study learning. Chicks will peck spontaneously at bright beads, and if the bead is dipped in a distasteful

substance, the chicks will peck once at the bead and show a strong disgust response. Subsequently, they will avoid pecking a similar but dry bead and learn this avoidance behavior. The strong emotional fear component involved in this passive avoidance response in chicks prompted Sandi and Rose to explore the role of stress hormones in learning in the chick. In tests of passive avoidance learning in the chick, they found that an inverted U-shaped curve emerged, in which low levels (0.1 μg) and higher levels (2 μg) of corticosterone were without effect, whereas an intermediate dose (1 μg) improved learning. Similarly, in rodents, an inverted U shape is seen between the dose of administration of corticosterone and performance in learning tasks. It has thus been seen that low doses of corticosterone can improve learning, whereas continuous exposure to glucocorticoids results in neuronal death in the hippocampus and in impaired learning ability. Aged rats that are impaired in cognitive function have elevated levels of corticosterone and increased hippocampal neuronal loss when they are compared with aged rats that are not impaired in cognitive function.

The effects of corticosterone on cognitive function are mediated through binding of the stress hormones to specific receptors in the brain. These receptors, known as glucocorticoid receptors, have been found to be abundant in the hippocampus, a brain region that is critically involved in modulating learning and memory. Another region in the brain that participates in cognitive function is the amygdala, which also has moderate amounts of receptors for corticosterone. The actions of corticosterone in the hippocampus and amygdala can be induced by the administration of selective drugs that interact with the glucocorticoid receptors. Drugs include those that enhance the effects of corticosterone (glucocorticoid agonists) or those that block or attenuate the effect of corticosterone (glucocorticoid antagonists). These drugs have provided powerful tools in dissecting the role of stress hormones in the hippocampus and amygdala in modulating cognitive functions in rodents. Pharmacological or environmental manipulation of the glucocorticoid receptors influences cognitive function in rats.

Hippocampus and Learning in Animals

Considerable evidence shows that the hippocampus mediates spatial learning in rodents. Spatial learning in rodents can be examined by the use of a water maze, known as the Morris maze. The procedure involves placing an experimental animal in a large pool of water of about 1.5 m in diameter. The animal has to use spatial cues in the experimental room to

locate an invisible escape platform that is hidden 2 cm below the surface of the opaque water. After a few days of testing, the animals learn to locate the platform within seconds. It has been demonstrated that rats perform poorly in this test if hippocampal function is impaired. Thus, aged rats with pathological changes in the hippocampus show impaired spatial learning in the water maze compared to aged rats that do not show pathological hippocampal changes. Aged rats that had been exposed to repeated restraint stress have a reduction in glucocorticoid receptors in the hippocampus. This results in, among other things, an impaired spatial learning ability. In contrast, animals that have higher levels of glucocorticoid receptors in the hippocampus show an increased ability for spatial learning. Administration of a glucocorticoid receptor antagonist in the brain appears to impair information processing during spatial learning.

To sum up, spatial memory in animals is dependent on hippocampal function. Through their action in the hippocampus, stress hormones facilitate spatial information processing so that low levels of corticosterone improve learning, whereas higher levels impair performance.

Amygdala and Learning in Animals

Many studies have concentrated on the effects that stress hormones have on the hippocampus and its relationship to learning. Work by James McGaugh and colleagues has begun to explore the role of stress hormone receptors in the amygdala on learning. The amygdala is a region of the brain that plays a crucial role in acquisition and expression of fear responses. This brain region is thought to influence memory storage processes in other brain regions, such as the hippocampus and cortex. An interaction of stress hormones and amygdala nuclei appears to be important in modulating memory consolidation for emotional events. Binding of glucocorticoid receptors in the basolateral nucleus is known to affect memory storage. It was found that administration of the glucocorticoid receptor agonist in this area immediately after training enhanced retention of a passive avoidance response. Many studies have examined the effects of glucocorticoids on the acquisition of newly acquired information. In a test of memory retrieval of long-term spatial learning memory, it was found that stress caused impaired performance, and this impairment could be related to circulating levels of corticosterone. These findings point to a critical involvement of the amygdala in regulating stress hormone effects on learning and memory.

To conclude, the amygdala is a region of the brain known to be importantly involved in emotions. Stress

hormones can affect the memory storage of emotional events by their actions on the amygdala. The impact of stress on the hippocampus and amygdala is highlighted by emerging evidence from animal studies that revealed that stress causes changes in hippocampal plasticity and can thus modify the information storage mechanism in the hippocampus and that the amygdala is involved in the emergence of stress-associated changes in the hippocampus.

Summary

Stress hormones have biphasic effects on learning and memory in animals. Low levels of stress hormones improve performance, whereas higher levels have a deleterious effect on learning. Two brain regions important in regulating learning and memory are the hippocampus and amygdala, which contain receptors for stress hormones. The effects of stress hormones on learning are mediated by these receptors in the hippocampus and amygdala. Research in rodents has revealed that emotional arousal regulates learning through the action of stress hormones, which activate receptors in the hippocampus and amygdala to affect memory formation.

Memory, Learning, and Their Anatomical Bases in Humans

Conceptualization of Learning and Memory

The contemporary conceptual frameworks of learning and memory emanate from experimental psychology. According to this model, human memory is not a unitary system, but is composed of a series of interdependent brain systems characterized by different features in terms of time for the registration of new information (immediate/extended in time), type of information (implicit/declarative or explicit), accessibility (immediate/search), amount of information stored (limited/unlimited), spontaneous duration of information in memory (limited/unlimited), and awareness of information (yes/no). These distinct memory systems appear to be subserved by separate neural networks, as shown by brain behavior studies and prior studies demonstrating specific effects on memory due to lesions in the brain.

One major division of memory is that between implicit or nondeclarative memory and declarative (explicit) memory. Nondeclarative memory includes procedural memory, classical conditioning, the perceptual representation system, and priming. In line with phylogenesis and ontogenesis, one early type is procedural memory, which is expressed as skilled behavior or motor procedures, which appear to be

suberved by regions in the basal ganglia. One division of procedural memory is classical conditioning, which is the same as a stimulus–response connection. The hippocampus and certain parts of the cerebral cortex have been identified as important areas for this memory system. Another type of implicit memory is the perceptual representation system, which is concerned primarily with the acquisition and use of perceptual objects of the world. The predominantly responsible brain areas are the primary association cortices. Another branch of implicit memory is priming, which refers to an unconscious ability to process a stimulus due to prior exposure. Declarative memory can be described as the conscious recollection of facts and events (Krystal et al., 1995). To this memory system belongs short-term memory or working memory, semantic memory, and verbal as well as visuospatial episodic memory. Short-term or working memory processes and stores temporarily a very limited amount of information. Semantic memory covers acquisition and use of factual knowledge about the world and is mapped by association areas in the brain. Information unique in time, location, and person is involved in storage and recall of information from episodic memory, for which the medial temporal lobes are one crucial point of the subserving neural networks. Another important aspect of memory is learning. Some authors equate long-term storage with learning, for example, calling it the process by which information that may be needed again is stored for recall on demand (Peterson, 1967). A broader definition is that learning is the same as the modification of behavior according to earlier experiences.

The Anatomy of Human Memory

The hippocampus thus plays an important role in several of the subdivisions of the two main memory systems. In the hippocampus, stimuli from the external world are classified and stored, momentarily in short-term memory and for longer periods of time in long-term memory, and the spatial and temporal dimensions of the experiences are recorded. It is doubtful, however, that the hippocampus is responsible for the more permanent consolidation of memories. Adjacent to the hippocampal system is the amygdala, which plays an important role in the processing of emotional information in the brain. The amygdala consists of several distinct nuclei, whose functional properties vary. The basolateral amygdaloid complex appears to be the nucleus that is involved most crucially in memory performance. However, it is not critical for the consolidation of a memory trace per se. Instead, it has been suggested that the

amygdala assigns emotional meaning to incoming free-floating feelings, integrates this emotionally meaningful information with associated emotional memories, and, through projections to the hypothalamus, hippocampus, and basal forebrain, directs emotional behavior. The amygdala also contributes to the enhancement of a memory trace that is related to emotional responses such as stress.

The frontotemporal area is the center for the executive function, short-term memory, and personality. This area of the brain has an elaborate network of connections to most other regions of the brain and a high concentration of stress hormone receptors, which has been found to assure the role of the frontal lobes in stress, learning and memory.

Vulnerability of Human Memory

The current conceptualization of human memory posits that the order of memory acquisition during ontogenesis, as described earlier, is reversed when the brain is exposed to various adverse influences such as aging, toxins, inflammatory agents, and stress. The meaning of this is that more sophisticated memory systems, such as declarative memory, are hit at an early stage, whereas more basic and ontogenetically earlier systems, such as procedural memory, are afflicted later on. Of course, the reversed order of degradation does not hold when there is a highly localized attack on the brain, as is the case for brain trauma. However, it is well known that episodic memory is highly sensitive for aging as well as for disease processes such as Alzheimer's disease. The next section describes changes that take place in relation to memory performance when humans are exposed to stress.

Encoding in Stressful Situations

Encoding is closely connected with attention and vigilance, which both influence the encoding of information into declarative as well as nondeclarative memory. Attention, like vigilance, is highly sensitive to stress. To be able to encode an all-embracing picture of an event, it is necessary that attention be unrestricted. During a stressful situation the attentional span tends to be narrowed to the most salient stimuli in the situation, whereas more peripheral stimuli are neglected. It has also been suggested that the hippocampus seems to shut down under severe stress, which may contribute to an incomplete encoding of the stressful situation. It has been demonstrated experimentally that people who have been exposed to pictures of a bloody car accident tend to remember central trauma-related items better than more

peripheral details. This laboratory finding is related to a real-world phenomenon called weapon focusing. Witnesses to crimes committed with visible weapons have sharper memories of the weapon than of other aspects of the situation, including the face of the perpetrator, for which the memories are more diffuse. The explanation for this is that the gun is the carrier of the most emotionally salient information and therefore captures the attention at the expense of other aspects. This phenomenon has been found to be particularly pronounced in people reacting with anxiety at the sight of weapons.

Short-term memory, which demands that information be held in consciousness momentarily, has been found to be extra sensitive to stress because the situation demands a focus on stress-relevant stimuli and therefore attention tends to be biased. On the contrary, overlearned abilities, such as procedural memory, for which the memory traces are well consolidated, are found to be more stress resistant than recently acquired memories, which are destroyed more easily. In a laboratory test of declarative memory, spatial thinking, and procedural memory tested with a word stem priming task, high levels of cortisol impaired declarative memory and spatial thinking, whereas procedural memory was spared.

One reason why overlearned skills are more difficult to erase is that repetition contributes to a better memory. Thus, it appears that more recently registered material in long-term storage and short-term memory is more sensitive to stress.

Effects of Anticipated Stress on Memory

It is not always being in the stressful situation that causes emotional arousal; the anticipation of the incoming stressor may have the same effect. In an experiment by Lupien and colleagues, a group of 14 healthy elderly persons was given a nonstressful task and a stressful task. The nonstressful condition consisted of a computer task. The stressful condition consisted of a videotaped public-speaking task, for which the discourse was said to be evaluated by experts. Before and after each condition subjects were given a declarative memory task and a nondeclarative word completion task. Results showed that in the responders (individuals who react to stress with an increase in cortisol levels), high levels of cortisol were secreted long before the stressful condition, which was not the case in the nonresponders (no change in cortisol level due to stress). This signifies that the anticipation of the incoming stressor played a more important role in the secretion of cortisol than the actual stressor. The responders also

performed worse on the declarative memory task than the nonresponders, indicating that even the anticipation of stress has a detrimental effect on declarative memory. Nondeclarative memory was spared. The stress did not affect the nondeclarative memory significantly, either in the whole group or in the subgroups.

One concluding remark about the effects of stress on learning and memory is that stress seems to influence the modulation of memories through its effects on attention and vigilance during the encoding of information. This may be true both for being in a stressful situation and for anticipating of a fear-provoking event. Knowledge about the biological and psychological mechanisms behind the effects of stress on attention and memory storage may help individuals gain control over these processes in order to perhaps make use of the positive effects of stress on memory and learning and avoid the negative.

Possible Mechanisms of the Relation between Stress and Memory

It is possible to differentiate among physiological, cognitive, and emotional stress, which sometimes may partly overlap. These types of stress might be analyzed from two angles: context and time, and whether the stress is good or bad for learning and memory. Two types of learning that are enhanced by stress are classical fear and eyeblink conditioning, as well as processes related to learning about threatening stimuli. In the standard paradigm of eyeblink conditioning, the Pavlovian eyeblink conditioning, a human is exposed to an air puff to the eye, which evokes an involuntary eyeblink reflex as an unconditioned response (UR). When the air puff is directly preceded by a sound as the conditioned stimulus (CS), the human learns the association between the tone and the air puff and blinks in response to the tone, thus anticipating the air puff. The blink is the conditioned response (CR) and is an example of associative learning. Here we are dealing with a physiological stressful event that generates, not disturbs, new associative learning. Physical stressors are generally said to activate lower brain regions involved in, e.g., pain responses, whereas psychological stressors engage the limbic structures.

Concerning the effects of stress on cognition, particularly learning and memory, one of the greatest challenges for neuropsychological research today is to determine the effects of stress on the different stages of the memory process. It is suggested that stress has differential effects on distinct phases of the learning and memory processes. Consolidation

of information is found to be enhanced by stress if the stress occurs concomitantly in time and in the same context as the thing to be remembered. The recall of information is impaired, however, if the system is exposed to stress shortly before the retrieval of information. One illustrative example of these conjunctions is given by Joëls et al. People passing a stressful examination may have difficulties in recalling the earlier learned, required information (impaired retrieval), but at the same time the traumatic experience of not remembering is burned deeply into their memories (enhanced consolidation). Retrieval difficulties have been interpreted as a negative consequence of the release of corticosteroid hormones. Inversely, the release of corticosteroid hormones facilitate new learning, which tends to compete with or overwrite the earlier acquired information. The competition between the access to earlier information and current challenges has been conceived as a kind of fruitful adaptation, since knowledge about new threats (i.e., risk of failure on the examination) may enhance the chances of future survival, in this context a better preparation for the next examination.

These findings are congruent with results showing that exposition for a psychological stressor preserves or enhances the memory for the emotional aspect of an event, while it simultaneously disrupts the memory for non-emotional or neutral aspects of the same event. This pattern may be explained by the fact that emotional and non-emotional memories are modulated by different structures of the brain. Encoding and retrieval of emotional memories are associated with the amygdala, whereas the encoding and retrieval of non-emotional memories are associated with the hippocampal formation. This pattern might also explain the gaps in memory and general memory impairment seen in patients suffering from traumatic memories.

Summary

Stress refers to an extra load on the organism. Neuroendocrinologically, stress reactions are characterized by the release of the stress hormones corticosterone in animals and cortisol in humans. Normally, increasing demands lead to increasing performance. However, this relationship holds up to a certain optimal level; thereafter, increasing demands lead to decreasing performance. This appears to be true for animal as well as human behavior in the domain of learning and memory. The mnemonic process in animals is characterized by associations between a few or several elements. Memory and learning in humans are more complex and may be

analyzed in two main systems: declarative and non-declarative memory. In animals as well as in humans, the same cerebral structures have been identified as crucial in the mnemonic process: the hippocampus and the amygdala. The hippocampus is critical for learning and memory, whereas the amygdala is responsible for the transmission of emotional information during the mnemonic process. Stress hormone receptors in the hippocampus and amygdala make these cerebral structures responsive to stress. The frontal lobes are also involved in the memory process, through the region's accumulation of stress hormone receptors and rich connections to other parts of the brain. It is possible to differentiate among physiological, cognitive, and emotional stress, which might be analyzed from a time and context perspective and with respect to whether they are good or bad for memory. Generally, declarative memory is more sensitive to stress than nondeclarative memory. Stress has different effects on the declarative memory depending on which phase in the memory process that it occurs.

ness of its walls. The size of the ventricle normally varies with the size of the person, so for comparative purposes it is customary to normalize left ventricular mass to body surface area, as the left ventricular mass index.

Glossary

Echocardiography

A noninvasive technique for visualizing the structure and function of the heart using ultrasound. In its simplest form, a single beam (m mode) of ultrasound is aimed at the heart from a transducer placed on the chest wall, and reflections are detected from the cardiac structures hit by the beam. Two-dimensional echocardiography uses an array of beams that give a two-dimensional picture of the heart. Because traces can be recorded over several cardiac cycles, it is possible to gain information about the function of the heart as well as its structure.

Left ventricular hypertrophy

A left ventricular mass index that is above the upper limit of normal for the individual's gender and body size.

Left ventricular mass

Mass of the muscle of the left ventricle of the heart, calculated from echocardiographic measurements of the size of the chamber of the ventricle and the thick-

ness of its walls. The size of the ventricle normally varies with the size of the person, so for comparative purposes it is customary to normalize left ventricular mass to body surface area, as the left ventricular mass index.

Left ventricular (LV) mass is the weight of the left ventricle, typically estimated using echocardiography, and is thought to represent the cumulative effect of blood pressure on the heart. It is normally closely related to body size and is greater in men than in women. It also increases with age. It correlates more closely with blood pressure measured over prolonged periods of time (e.g., over several years in the Framingham heart study or by 24-h blood pressure monitoring) than with routine office measurements, but this correlation does not exceed 0.5, so that only 25% of the variance of LV mass can be explained by the blood pressure level. LV hypertrophy (defined as an LV mass that exceeds the normal range) is seen in about 30% of people with hypertension and is more common in older and more obese patients. The importance of LV mass also lies in the fact that it is an independent risk factor for cardiovascular morbidity; in fact, no other biological variable apart from age predicts cardiac risk better than LV hypertrophy. This may be partly because it represents a superior measure of the effects of increased blood pressure on the circulation, but it may also have direct pathological

significance. Thus a high LV mass is associated with a decreased coronary flow reserve (i.e., the heart outgrows its blood supply) and it also makes the heart more susceptible to arrhythmias. Treatment of hypertension with either drugs or lifestyle measures (e.g., weight reduction) can reduce LV mass, and there is some evidence that the regression of LV hypertrophy is associated with an improved survival.

LV mass is usually measured by echocardiography, which is considered to be the gold standard. This is a noninvasive ultrasound test performed by holding an ultrasonic probe on the chest wall, which emits a single beam (m mode) or a two-dimensional array of beams, and detects the reflected beams from the tissues of the heart. Magnetic resonance imaging also enables visualization of the heart and may give an even more accurate assessment, but is also much more expensive.

While blood pressure is one of the major determinants of LV mass, there are others that may be of equal significance. Twin studies have shown that there is a genetic component, which may be linked closely to the genetic regulation of body weight. LV mass is related to salt intake, and the activity of the sympathetic nervous system and renin-angiotensin systems may also increase it; in healthy young adults, plasma angiotensin II is one of the determinants of LV mass. Like 24-h ambulatory blood pressure, measures of LV geometry, including LV mass and wall thickness, have provided important information about the significance of behavioral factors relating to heart disease due to hypertension. Studies have shown that occupational stress (measured as job strain) in men is associated not only with hypertension, but also with increased LV mass. The propensity to show exaggerated blood pressure responses to stress may also be associated with greater LV mass in African-American and white adolescents and adults. What remains uncertain is the causal relationship between these observations: (1) it could be that the increased LV mass is associated with structural changes in the arteries, which are responsible for the increased reactivity; (2) the left ventricle could produce an exaggerated response leading to the increased reactivity; or (3) the increased reactivity could be the cause of the increased LV mass. For the same level of clinic blood pressure, African-Americans have a greater LV mass

than white people. The reason for this is unknown, but one contributory factor could be the comparatively higher nocturnal blood pressure in black people.

Glossary

<i>Amastigote</i>	The life stage that resides within mammalian hosts, mostly in macrophages. An obligatory intracellular form.
<i>Cutaneous leishmaniasis</i>	A form of leishmaniasis that produces skin lesions, usually self-healing (<i>L. major</i> , <i>L. amazonensis</i>).
<i>Leishmania</i>	A protozoan parasite that belongs to the Kinetoplastida order. The parasites cycle between sand fly vectors and mammalian hosts, causing a wide range of clinical manifestations.
<i>Metacyclic form</i>	The infective life stage that resides in the sand fly vector, mainly in the proboscis.
<i>Mucocutaneous leishmaniasis</i>	A form of leishmaniasis in which the mucosal organs, primarily the nose and mouth, are attacked (<i>L. braziliensis</i> , <i>L. amazonensis</i>).
<i>Promastigote</i>	The parasite life stage that resides within the intestinal tract of the sandfly vector.
<i>Visceral leishmaniasis</i>	A systemic form of leishmaniasis in which visceral organs, mainly the liver and spleen, serve as targets for infection by parasites. Visceralization occurs in infections by certain species, such as <i>L. donovani</i> , <i>L. infantum</i> , and <i>L. ethiopica</i> . The disease is lethal if left untreated.

Leishmania: The Organism and Its Life Cycle

Leishmania parasites are flagellated diploid protists that belong to the order Kinetoplastida. This order is named after the kinetoplast, a unique organelle that harbors the mitochondrial DNA. Parasites of the genus *Leishmania* are the causative agents of a broad spectrum of human diseases. Different species of *Leishmania* vary in their clinical manifestations, ranging from lesions of the skin and mucosal organs to the lethal visceral form. Drug treatment is available, though toxic, and there is yet no safe vaccine available. *Leishmania* are distributed in large areas of the old and new world, causing both morbidity and mortality.

The parasites lead a digenetic life cycle, migrating between insect vectors and mammalian hosts. They exist as extracellular flagellated promastigotes in the alimentary tract of the sand fly vector. Promastigotes from the midgut of the sand fly are noninfective; however, upon proliferation they differentiate from procyclics into a virulent metacyclic form and migrate to the front part of the intestinal track. During the blood meal of female flies, the parasites are transmitted to the mammalian host, where they become obligatory intracellular amastigotes that reside within the phagolysosome vacuoles in macrophages. At all life stages *Leishmania* encounter hostile environments, which are characterized by high hydrolytic and proteolytic activities. Moreover, the parasites are exposed to growth conditions that differ significantly between vector and host in temperature, pH, nutrients, and serum components. Survival of *Leishmania* is facilitated by mechanisms that allow tolerance to pH and temperature shifts and resistance to complement lysis and to oxidative stress in the macrophage. Transformation includes morphogenesis and changes in metabolism and in enzymatic activities, as well as in the abundance of surface molecules. The adaptation necessary for parasite survival is acquired by alterations in gene expression, which can be modulated by the changing environment. The ability of *Leishmania* parasites to withstand the wide range of unfavorable conditions leads to their high virulence and therefore has been extensively studied.

Axenic Amastigotes: The Stress Response as a Differentiation Trigger

It has been well established that stage transformation of *Leishmania* parasites from promastigotes to amastigotes can be induced axenically upon exposure to elevated temperatures and reduced pH, conditions that mimic the environment in the mammalian host. Thus, in several *Leishmania* species, stage transformation may occur without a requirement for internalization within macrophages or other cells of the immune system. This has been shown for species of the new world, such as *L. amazonensis*, as well as for species that are distributed in the old world, such as *L. donovani*. Titration of the response to a gradual temperature elevation shows that axenic transformation is temperature restricted. It involves the increased synthesis of heat shock proteins; however, above a certain temperature threshold, translation of all other cellular proteins stops completely, preventing proper differentiation. Thus, axenic differentiation is restricted to a narrow range of temperatures, and above a certain threshold the parasites will die rather than transform. The temperature threshold varies for different species: the heat shock response in the visceralizing *L. donovani* parasites occurs at 39°C, whereas in *L. amazonensis*, a cutaneous disease agent, the stress response is induced at 33°C.

A host-free differentiation system for *L. donovani* was used to investigate the initial process of differentiation, by monitoring the induction of additional stage-specific genes. Within 1 h of exposing promastigotes to the differentiation signals that combine temperature elevation (37°C) and exposure to acidic pH (5.5), expression of the amastigote-specific A2 protein family was observed. At 5 h, morphological changes such as elimination of the flagellum and rounding up of the cells were observed, and the process was completed 7 h later. This morphological transformation occurred synchronously, while the cells were arrested at G1. Sequential exposure to elevated temperature (for 24 h) and acidic pH conditions indicated that heat was responsible for the growth arrest and the acidic pH was required for the actual completion of differentiation into amastigotes. Other inducers of the stress response such as ethanol and azetidine-2-carboxylic acid (a synthetic proline analog) were capable of replacing the heat treatment as a differentiation signal.

Expression of heat shock proteins is tightly associated with stage differentiation in *Leishmania*. Although members of the Hsp83 and Hsp70 proteins are abundantly expressed throughout the life cycle, the steady-state level of transcripts encoding these proteins increases in amastigotes, along with their

preferential translation. Exposure of *Leishmania* parasites to geldanamycin, a drug that binds the ATPase site of Hsp90 and inactivates it, induces a stress response and triggers the differentiation process from the promastigote to amastigote life stage. In the presence of geldanamycin, expression of amastigote-specific genes such as A2 increases, and the cells transform into aflagellated and rounded amastigote-like cells. This effect of the drug is specific to *Leishmania* and is not observed with *Trypanosoma cruzi*, for example, suggesting that the differentiation signals may vary between these two kinetoplastids.

As indicated, Hsp90 and Hsp70 are expressed in all life stages, although their regulatory pattern changes in response to the changing environment. However, it has been shown that thermotolerance is associated with Hsp100, which is expressed mainly in the amastigote stage of *Leishmania*. Knock-out mutants depleted from Hsp100 delay the development of skin lesions in infected mice, but did not have an apparent effect on growth of promastigotes. Virulence is partly recovered upon introduction of the missing gene into the knock-out parasite strain. The association of Hsp100 with thermotolerance has been shown for other organisms such as yeast, and it appears that this protein plays a similar role in *Leishmania*.

Gene Regulation in *Leishmania*: Studying Heat Shock Genes as Models

Genome sequencing projects of *L. major*, *T. cruzi* and *T. brucei* have been accomplished, and the sequencing of additional trypanosomatid genomes is currently under way (*L. infantum* and *L. braziliensis*). Protein-coding genes are arranged in huge unidirectional clusters that cover large portions of the chromosomes and are transcribed polycistronically. The mature, monocistronic transcripts are excised by *trans*-splicing and polyadenylation. *Trans*-splicing involves the addition of a short, capped leader to the 5' end of the RNA, which is donated by an independent RNA molecule, denoted spliced leader RNA (SL RNA). Thus, capping of mRNAs is independent of the transcribing RNA polymerase, as in other eukaryotes.

Adaptation of trypanosomatids to different environments requires a tight control of gene expression. However, as a consequence of polycistronic transcription of protein coding genes, developmental regulation occurs posttranscriptionally by RNA processing, RNA stability, and translation efficiency. This has been established using heat shock genes as a model system, and unlike in most eukaryotes, transcriptional activation of these genes has been completely ruled out in *Leishmania*. The absence of transcriptional

activation of protein coding genes fits well with the genomic organization of protein coding genes in *Leishmania* and their polycistronic transcription.

Splicing during Heat Shock

In higher eukaryotes, RNA splicing is disturbed by heat shock. Thus, heat shock genes often lack introns, except for Hsp83 in *Drosophila*. As a result, splicing of the hsp83 RNA is improved if a mild heat shock precedes a more drastic temperature stress. In *Leishmania*, temperature elevation also affects *trans*-splicing in a stage-specific manner. For example, tubulin expression is altered during the life cycle. In the amastigote stage, the flagellum is adsorbed and the subpellicular microtubules do not reach the tip of the cells, causing them to round up. In accordance, processing intermediates of α -tubulin mRNAs accumulate at elevated temperatures. Counterwise, processing intermediates of Hsp70 can be seen only at 26°C, and not at mammalian like temperatures. This is in agreement with the increased steady-state levels of Hsp70 mRNAs that are observed in amastigotes.

RNA Stability during Heat Shock

Expression of stage-specific genes can be achieved by their differential stability at altered temperatures. Thus, transcripts of promastigote-specific genes are rapidly degraded at elevated temperatures, whereas transcripts encoding for heat shock genes, such as Hsp70 and Hsp90, are differentially stabilized at elevated temperatures. The stability determinants of these transcripts are found in their 3' untranslated regions (UTRs), although they could not be associated with a specific sequence element. Almost any deletion in the 3' UTR eliminated the preferential stability of the Hsp83 mRNA at elevated temperatures, suggesting that stabilization was acquired due to a specific RNA structure, which was sensitive to any change in the sequence of the 3' UTR. Temperature control over RNA stability was observed for other genes that are differentially expressed throughout the life cycle, such as the gene encoding for a promastigote-specific protein kinase A (PKA). The PKA transcript has a much shorter $T_{1/2}$ at mammalian-like temperatures as compared to 26°C, the temperature at which promastigotes are grown. Thus, it is abundant in promastigotes but can hardly be detected in amastigotes. Control of transcript abundance during the life cycle of *Leishmania* by temperature and pH shifts was reported for the amastigote-specific A2 gene and the promastigote-specific surface protease gp63.

Preferential Translation at Elevated Temperatures

Similar to higher eukaryotes, *de novo* synthesis of heat shock genes in *Leishmania* increases dramatically at elevated temperatures, as observed in metabolic labeling experiments that measure directly the nascent incorporation of amino acids into polypeptide chains. This pattern of regulation can be transferred onto a transfected reporter gene, which is flanked by genomic sequences that include the UTRs on both sides of the coding gene, along with adjacent processing signals. Using a series of reporter constructs, it was shown that unlike in other eukaryotes, preferential translation in *Leishmania* is controlled mainly by the 3' UTR of the Hsp83 gene, whereas the 5' UTR alone can improve the effect of the 3' UTR but cannot function alone in directing preferential translation. A similar observation was made for preferential translation of the Hsp70 gene, which is also controlled by the 3' UTR. Furthermore, two types of 3' UTR were found for Hsp70 genes, which differ in their ability to promote differential accumulation and translation at elevated temperatures, enabling expression at a broad range of conditions.

Translation regulation that is based on the 3' UTR varies from what we know for Hsp70 in higher eukaryotes, where preferential translation is directed by the 5' UTR. Great efforts were invested in understanding the mechanism that promotes and increases translation of heat shock genes at elevated temperatures in higher eukaryotes. Preferential translation cannot be assigned to binding of a specific protein factor to the 5' UTR, and different reports have suggested potential mechanisms for directing preferential translation. For example, the 5' UTR of heat shock genes is rich in adenosines and thus has minimal secondary RNA structures. Since heat shock impairs the ability to unwind RNA structures, which are common in 5' UTRs of non-heat shock genes, only mRNAs with minimal structures can be efficiently translated. Another report showed that the 5' UTR of Hsp70 contains boxes of sequence complementarity with the 18S rRNA, which may facilitate ribosome shunting, a mechanism by which the 40S ribosomal subunit binds the cap and bypasses large segments of the mRNA to reach the initiation codon. Preferential translation of *Drosophila* Hsp90 is also controlled by the 5' UTR, but nucleotides close to the first AUG were implicated as essential for preferential translation at elevated temperatures.

In *Leishmania*, the 3' UTR of the Hsp83 transcript appears to confer preferential translation at elevated temperatures. Deletion analysis mapped the regulatory region that controls translation of Hsp83 in *Leishmania* to sequences 201–472 of the 886-nt-

long 3' UTR. This element is required for preferential translation of a fused reporter gene at elevated temperatures. Interestingly, it functions irrespective of transcript stability. However, the minimal fragment that can induce preferential translation of a reporter gene is larger and requires the presence of the proximal half of the 3' UTR (nts 1–472). Furthermore, mutations in the 3' UTR that eliminate the increased stability of the mRNA do not affect their preferential translation at elevated temperatures, as long as the regulatory region is present in the 3' UTR. The requirement for a relatively large regulatory region supports the possibility that a discrete RNA structure is required for promoting preferential translation during heat shock. However, to date, no specific proteins that bind to this region have been identified, and it is not clear how this 3' UTR element functions.

Another 3' UTR control element sized 450 nts directs preferential translation of amastigote-specific genes and appears to be conserved between the 3' UTR of amastin and Hsp100 of *Leishmania*. The large size of this control region may also support a potential involvement of a specific RNA structure in regulating translation of amastigote-specific genes at elevated temperatures and acidic pH. RNA structure is known to be temperature sensitive and can even serve as a thermosensor molecule in prokaryotes, as well as in eukaryote organisms.

Heat Shock and Cell Death in *Leishmania*

Environmental stress conditions may cause multiple cell damages that include protein misfolding. Heat shock proteins can function as dedicated molecular chaperones in assisting the unfolding of damaged proteins and their proper refolding during recovery from stress. However, when repair is beyond reach, cells must be eliminated. Thus, events that are triggered by cell stress are closely associated with the decision process that targets a cell for its death. Programmed cell death (PCD) is a process that prevails in multicellular organisms, but an increasing number of reports indicate that single-celled organisms can die following a process that partly resembles PCD. Several apoptotic-like processes have been described in *Leishmania*; however, the issue of apoptotic death in this parasite is still controversial. Apparently, exposure of *Leishmania* to extreme conditions triggers stage differentiation rather than cell death. Despite their resistance to a broad range of environmental conditions, it is possible that upon passing a certain threshold, a PCD-like process will be induced. Preliminary reports indicate that stationary phase parasites of *L. donovani* present some of the basic features

typical of PCD in response to treatment with antileishmanial drugs such as amphotericin B. These include nuclear condensation, nicked DNA in the nucleus, DNA ladder formation, increase in plasma membrane permeability, decrease in the mitochondrial membrane potential, and induction of a specific cysteine proteinase activity. Exposure to extreme temperatures also resulted in cell death, which could be rescued in part by overexpression of Bcl-X(L). Despite these results, major differences are observed between the apoptotic death in higher eukaryotes and the death process in *Leishmania*, trypanosomes, and other unicellular protists, such as *Tetrahymena* and *Dictyostelium*. It appears that lower eukaryotes possess the basic machinery that can drive cell death; however, the pathway of this process in these organisms is different from that found in multicellular organisms. Further studies are required to understand whether these PCD features are associated with the life cycle of *Leishmania* parasites.

Redox Control, Oxidative Stress, and *Leishmania*

Another type of stress faced by *Leishmania* parasites is oxidative stress. *Leishmania* parasites reside within macrophages, and cells of the immune system can inhibit the oxidative burst of their host cells. However, despite this feature, a strong system for detoxification of oxyradicals is also required. Thiol metabolism varies between *Leishmania* and their invertebrate vector or mammalian host cells. Redox control in kinetoplastid parasites is mediated by trypanothione, a compound that substitutes glutathione in defending the cell against chemical and oxidative stress. Trypanothione, the major reducing thiol molecule in *Leishmania* and other trypanosomatids, consists of a spermidine moiety that is linked with two glutathione molecules. It is of major importance for parasite survival, since the parasites reside within mammalian macrophages, which specialize in generating oxyradicals. It is also interesting to note that trypanothione and its metabolic pathway serve as a target for the popular antimony-based drugs. Moreover, trypanosomes lacking trypanothione reductase are avirulent and show increased sensitivity to trivalent arsenicals and oxidative stress.

Kinetoplastids, including *Leishmania*, do not encode for the glutathione S-transferase gene, and they also lack the enzyme catalase. Instead, they express the trypanothione S-transferase, which in *L. major* is associated with the eukaryotic translation elongation factor 1B (eEF1B). This association could have impli-

cations for translational control by sensing the redox state of thiol groups on proteins in the cell.

Summary

Leishmania is a parasitic protozoan that cycles between an invertebrate vector and a mammalian host and thus experiences a broad range of environmental conditions as part of its natural life cycle. Environmental stresses serve as a trigger for the parasite to differentiate from one life form to another, and as an obvious outcome, heat shock genes are abundantly expressed. Due to their conserved mode of regulation among eukaryotes, heat shock genes serve as an ideal system to study the unique molecular features of *Leishmania*, a very early and interesting eukaryote.

Introduction

Adipose Tissue

Gastrointestinal Tract: Ghrelin

Conclusion

Glossary

<i>Adipocytokine</i>	Cytokines secreted by adipose tissue (i.e., leptin, adiponectin, and resistin).
<i>Adiponectin</i>	Hormone secreted by fat cells that modulates several physiological processes, such as glucose and fatty acid metabolism. Decreased plasma adiponectin levels are associated with obesity, insulin resistance, type 2 diabetes mellitus, and atherosclerosis.
<i>Adipose tissue</i>	Specialized connective tissue composed of fat cells (adipocytes), which store droplets of fat in the form of triglycerides and have many other important metabolic roles.
<i>Adipostatic peptide</i>	An agent that prevents adipocyte/fat cell accumulation.

Anorexia nervosa

Anorexigenic peptide
Cachexia

Cytokine

Ghrelin

Insulin

Leptin

An eating disorder that occurs most frequently in adolescent females and is characterized by the lack or loss of appetite, known as anorexia. Other features include excessive fear of becoming overweight, body image disturbance, significant weight loss, refusal to maintain minimal normal weight, and amenorrhea. An agent that transiently depresses food intake.

Extreme weight loss, usually associated with chronic disease.

A protein secreted by inflammatory leukocytes but also by nonleukocytic cells; cytokines act as intercellular mediators and differ from classic hormones in that they are produced by a number of tissues or cell types rather than by specialized glands.

A peptide produced and secreted from stomach that stimulates growth hormone release and, in addition, increases appetite and food intake.

A protein hormone secreted by the pancreas that plays a major role in the regulation of glucose metabolism, promoting the cellular use of glucose; also an important regulator of protein and lipid metabolism.

*Orexigenic
peptide
Resistin*

A hormone secreted by fat cells and implicated in the regulation of food intake and energy balance, depressing appetite and increasing energy expenditure. An agent that stimulates food intake.

A hormone secreted by fat cells that may play a role in insulin resistance and inflammation associated with obesity.

Introduction

Obesity has become a public health problem due to its increasing prevalence and associated morbidity and mortality, mainly from cardiovascular disease, type 2 diabetes, and certain malignancies. In addition to a genetic predisposition, environmental factors, physical inactivity, a high-energy high-fat diet, smoking, and stress (which results in dysregulation of endogenous hormones) strongly contribute to the development of this multifactorial disorder.

Obesity is known to be associated with insulin resistance and development of the metabolic syndrome. However, not all obese patients are insulin-resistant and total fat mass *per se* is not the most important factor contributing to insulin resistance but, rather, the presence of central or visceral obesity. Central obesity has been associated with the dysregulation of the hypothalamic-pituitary-adrenal (HPA) axis and the sympathetic nervous system. The stress hormones of the HPA axis (i.e., cortisol) and the sympathetic system (catecholamines) oppose the effects of insulin, and this may promote insulin resistance. A chronically stressed HPA axis leads to decreased circadian variations in circulating cortisol levels, and chronic glucocorticoid exposure may lead to increased food intake and obesity.

In parallel with the increasing prevalence of obesity, there has been a tremendous increase in research activity in a global effort to better understand energy balance and the regulation of metabolism and body weight. Although a biological basis for body fat regulation was first proposed more than 50 years ago, the hypothesis of an endocrine feedback loop regulating body weight remained elusive until the discovery of the adipocyte-secreted hormone leptin in 1994. This discovery has dramatically changed our understanding of adipose tissue from an inert depot of energy storage to an active organ producing and secreting various molecules that regulate metabolism and energy homeostasis, such as leptin, adiponectin, and resistin (see Table 1). In addition, it has recently been recognized that other peripheral organs, such as the gastrointestinal tract, secrete molecules that also convey information on energy intake and balance. For exam-

ple, ghrelin, a novel gastrointestinal tract-secreted peptide, not only stimulates the secretion of growth hormone (GH) from the pituitary but also plays an important role in energy homeostasis, causing a positive energy balance by stimulating food intake.

The currently accepted model of energy homeostasis proposes that peripheral signals, such as molecules secreted into the circulation from the gut and the adipose tissue, are received and integrated by the central nervous system together with other signals/modulators of food intake and energy homeostasis, such as visual stimuli, smell, the presence of food, social habits or social behavior, and stress, with the final purpose to match food intake with energy expenditure. Signals from both adipose tissue and other peripheral organs not only are processed centrally in the brain to control body metabolism and energy but may also influence other physiological functions, such as the neuroendocrine and reproductive systems.

Various central and peripheral factors involved in energy homeostasis are being continuously discovered, and it is expected that a better understanding of these mechanisms will lead to effective treatments for the control of metabolism and obesity. This review discusses the potential role of four recently discovered molecules involved in metabolism and energy homeostasis: leptin, adiponectin, resistin, and ghrelin.

Adipose Tissue

The adipose tissue is considered today to be a very active and complex endocrine organ. Adipocytes produce and secrete a variety of bioactive molecules, including adipokines, which act at both the local (paracrine/autocrine) and systemic (endocrine) levels to exert diverse metabolic functions. These adipokines include leptin, tumor necrosis factor (TNF)- α , and interleukin (IL)-6, which have already been intensively studied, as well as newer molecules, such as adiponectin and resistin, which may prove to have important roles in controlling metabolism and energy homeostasis.

Leptin

Leptin (from Greek *leptos*, thin) is a 167-amino-acid protein discovered in 1994 as the product of the obese (*ob*) gene. Although known to have numerous other physiological functions in mice and humans, leptin is primarily involved in the control of the neuroendocrine and immune response to energy deprivation. Leptin is produced predominantly by adipose tissue and is secreted into the circulation at levels that are directly proportional to fat mass. Leptin is also expressed at low levels in the hypothalamus,

Table 1 Adipocytokines and ghrelin: effects on energy homeostasis^a

<i>Molecule</i>	<i>Site of production</i>	<i>Circulating levels</i>	<i>Target organ/tissue</i>	<i>Effect on insulin sensitivity</i>	<i>Effect on energy expenditure</i>	<i>Stress interaction</i>	<i>Other effects</i>
Adiponectin	Adipose tissue (primary)	Decreased in obesity, type 2 DM, CVD, malignancies	Muscle	Increases insulin sensitivity Stimulates glucose uptake Stimulates fatty acid oxidation Decreases gluconeogenesis	Increases energy expenditure Decreases body weight without affecting food intake (ICV administration)	Exo- or endogenous glucocorticoids inhibit adiponectin secretion	Anti-inflammatory Anti-atherogenic Anti-carcinogenic
	Cardiomyocytes ^b Placenta ^b		Liver Hypothalamus (PVN nucleus)				
Ghrelin	GI tract: stomach (enterochromaffin cells) (primary)	Increased acutely before each meal	Pituitary (GH-releasing cells)	May reduce insulin sensitivity	Decreases energy expenditure	Ghrelin stimulates ACTH release and activates HPA	Increases gastric motility and acid secretion
	Hypothalamus (ARC nucleus)	Decreased in obesity	Hypothalamus (NPY and AgRP neurons)	Decreased glucose disposal rate during ghrelin infusion	Increases appetite and stimulates food intake	Acute psychological stress raises plasma ghrelin in rodents	Reduces locomotor activity
		Elevated in anorexia nervosa or cachexia		Increases GH release Enhances the use of carbohydrates and reduces fat use	Reduces thermogenesis	Activation of gut sympathetic nerves stimulate ghrelin secretion	
Leptin	Adipose tissue (primary)	Increased in proportion to body fat	Hypothalamus (ARC) Brain stem	Increases insulin sensitivity Stimulates glucose uptake Stimulates free fatty acid oxidation	Increases energy expenditure Decreases appetite, food intake, and body weight Increases sympathetic activity Stimulates thermogenesis	Suppresses the activity of the HPA axis (CRH, ACTH, cortisol) Glucocorticoids stimulate leptin secretion, but excess may contribute to leptin resistance	Stimulates reproductive and thyroid functions Stimulates immunity Inhibits bone formation
	Hypothalamus ^b Pituitary ^b Placenta ^b Skeletal muscle ^b Gastric and mammary epithelia ^b						
Resistin	Adipose tissue Mononuclear leukocytes Macrophages	Variable in obesity	Liver ? Muscle ? Hypothalamus ?	Decreases insulin sensitivity in rodents (impairs insulin action on hepatic glucose production and may decrease fatty acid oxidation) Controversial in humans	May decrease energy expenditure in rodents Controversial in humans	Unknown	Inhibits adipocyte differentiation in rodents May have pro-inflammatory effects

^aACTH, adrenocorticotrophic hormone; AgRP, agouti-related protein; ARC, arcuate nucleus; CRH, corticotropin releasing hormone; CVD, cardiovascular disease; DM, diabetes mellitus; GH, growth hormone; GI, gastrointestinal; HPA, hypothalamic-pituitary-adrenal; ICV, intracerebroventricular; NPY, neuropeptide Y; PVN, paraventricular nucleus.

^bAt low levels.

pituitary, placenta, skeletal muscle, and gastric and mammary epithelia. Leptin is found in the peripheral circulation in both a free and a bound form; the free form crosses the blood–brain barrier, binds to the long isoform of a specific leptin class 1 cytokine receptor (also known as ObRb) and activates mainly the janus kinase (JAK)–signal transducer and activator of transcription (STAT) and phosphatidylinositol 3 (PI3)–AKT pathways to convey information to the central nervous system regarding the amount of energy stored in adipose tissue and acute changes in caloric intake. Leptin receptors are predominantly found in the hypothalamus, mainly in the arcuate nucleus but also in the brain stem and other regions of the central nervous system. The activation of hypothalamic receptors stimulates the production of anorectic peptides, such as α -melanin-stimulating hormone (α -MSH) and cocaine and amphetamine-regulated transcript (CART), and inhibits the production of orexigenic peptides, such as neuropeptide Y (NPY) and agouti-related peptide (AgRP), resulting in the inhibition of appetite. In addition, leptin binding to hypothalamic receptors results in increased sympathetic activity, which stimulates free fatty acid oxidation and thermogenesis in brown adipose tissue, thus favoring energy expenditure in mice.

Leptin expression is mainly controlled by the amount of body fat mass; caloric restriction and weight loss results in decreased circulating leptin levels, whereas overfeeding and increasing adipose tissue mass results in increased leptin levels. Leptin production and secretion is also increased by insulin, glucocorticoids, TNF- α , and estrogens; it is decreased by β_3 -adrenergic activity, androgens, free fatty acids, growth hormone, and peroxisome proliferator activated receptor (PPAR)- γ agonists.

The direct involvement of leptin in the regulation of energy intake and expenditure (by signaling the adequacy of energy stores to the brain) was initially demonstrated in studies in mice. Mutations in the obese (*ob*) gene (leptin gene) and the diabetes (*db*) gene (leptin receptor gene) result in morbid obesity and diabetes, whereas the administration of leptin to leptin deficient (*ob/ob*) and normal rodents results in significant weight loss. However, diet-induced obese mice, the mouse model of obesity that most closely corresponds to garden-variety obesity in humans, are not able to lose weight significantly after leptin administration, indicating that these hyperleptinemic mice are leptin resistant, probably due to receptor or postreceptor defects.

Similarly, only a distinct minority of morbidly obese human subjects have congenital leptin deficiency due to mutations of the *ob* gene, which result in hyperphagia and early-onset, rapid weight gain. The

administration of exogenous leptin to these patients results in the normalization of their hyperphagia, decreased caloric intake, and a significant loss of fat mass. Rare inactivating mutations of the leptin receptor gene have also been reported, which, similar to leptin gene defects, manifest clinically with hyperphagia and extreme obesity, as well as hypogonadotropic hypogonadism, but they are also associated with growth delay and secondary hypothyroidism. Our studies have shown that increasing leptin levels precede the onset of puberty, suggesting that leptin may be a permissive factor for the onset of puberty in humans.

Although exogenous leptin administration is an effective treatment, resulting in significant weight loss in obese leptin-deficient subjects, the majority of the cases of human obesity do not respond to leptin therapy. It is now known that most obese individuals have increased leptin production and secretion from adipocytes as well as high circulating leptin levels, features that are consistent with a state of leptin resistance. Several mechanisms are involved in the leptin resistance of obese individuals, including defective transport of leptin across the blood–brain barrier into the brain and/or reduced hypothalamic leptin signaling, in part due to the upregulation of specific inhibitors of leptin signaling. A complete understanding of the pathogenesis of leptin resistance in humans may open new pathways for the treatment of obesity.

Interestingly, a small study reported that exogenous leptin administration to replace leptin levels to preweight-loss levels, prevented the regaining of weight, and promoted the loss of fat mass in a small group of subjects participating in a weight loss program. These findings need to be confirmed by larger studies.

There is accumulating evidence that leptin has complex neuroendocrine functions, regulating the activity of the HPA and also the hypothalamic-pituitary-gonadal and -thyroid axes. It has been reported that leptin suppresses the activity of the HPA; that is, decreased leptin levels during fasting/starvation are associated with increased activation of the HPA and cortisol secretion. In accordance with this, in critically ill patients the nocturnal fall in leptin levels is associated with a paradoxical increase of nocturnal adrenocorticotrophic hormone (ACTH) and cortisol levels. Leptin-deficient mice and humans fail to go through puberty, and leptin administration reverses this abnormality. We have shown that the decreased leptin levels found in food deprivation are responsible for the starvation-induced suppression of the hypothalamic-pituitary-gonadal axis as well as changes in the function of other neuroendocrine axes in humans. In addition, extremely thin women with hypothalam-

ic amenorrhea have low leptin levels and exogenous leptin administration normalizes their neuroendocrine and reproductive functions. Thus, it seems that leptin may act as the critical link between adipose tissue and not only hypothalamic centers regulating energy homeostasis but also the reproductive system, indicating whether adequate energy reserves are present for normal reproductive function. Further larger trials are needed to conclusively prove whether leptin replacement treatment can ameliorate or treat the neuroendocrine dysfunction and also the immune abnormalities, osteoporosis, and infertility in women with hypothalamic amenorrhea.

In addition to signaling in the central nervous system, leptin also acts in the periphery and has important roles in regulating insulin action and lipid metabolism. Other peripheral endocrine effects include the direct regulation of immune function, hematopoiesis, angiogenesis, and direct and indirect effects on bone metabolism.

Taken together, these findings suggest that leptin plays a significant role in the central regulation of energy balance and that leptin is a critical signal for neuroendocrine function in humans; this raises the possibility that leptin is indeed not only an adipostatic hormone but also a stress-related hormone crucial for survival.

Adiponectin

Adiponectin (Acrp30, apM1 protein, adipoQ, or GBP28) is a 247-amino-acid protein discovered simultaneously by four different research groups in the mid-1990s. Adiponectin is produced and secreted exclusively by differentiated adipocytes and represents one of the most abundant serum proteins that circulates in tightly associated trimers and higher-order oligomers. Eight adiponectin isoforms with variable potency have been isolated, which bind and activate at least two adiponectin receptors. Adiponectin receptor 1 (AdipoR1) is expressed ubiquitously but most abundantly in skeletal muscle and has a high affinity for globular adiponectin and a very low affinity for full-length adiponectin; adiponectin receptor 2 (AdipoR2) is found predominantly in the liver and has an intermediate affinity for both forms.

Adiponectin decreases with increasing overall and central adiposity and increases with prolonged weight reduction. In humans, although short-term fasting does not influence circulating levels of adiponectin, prolonged caloric restriction results in weight loss and increased adiponectin levels. In addition, daily caloric intake, macronutrient intake, and high fat intake do not correlate with and do not affect circulating adiponectin levels in humans, except possibly in obese individuals, but a Mediterranean-type diet,

which has beneficial effects on morbidity and mortality, increases adiponectin levels. Interestingly, studies in rodents have revealed that central and peripheral adiponectin administration increases energy expenditure by stimulating free fatty acid oxidation and glucose uptake, thus reducing body weight and visceral adiposity without affecting energy intake.

Although its role has not been definitively established, there is accumulating evidence that adiponectin regulates insulin sensitivity and is also involved in inflammation and atherosclerosis. Initial animal studies showed that adiponectin-knockout mice develop insulin resistance either independently of diet or only after high-fat and high-sucrose diet, whereas adiponectin treatment improves their insulin resistance. In addition, lipoatrophic and obese mice have low adiponectin levels and insulin resistance, which improve partially after exogenous adiponectin administration. Moreover, the decrease in circulating adiponectin levels parallels the development of insulin resistance and type 2 diabetes in a longitudinal study of rhesus monkeys.

Studies in humans showed that there is a negative correlation of adiponectin levels with fasting glucose, insulin, and insulin resistance and a positive correlation with insulin sensitivity, independent of body-mass index (BMI). We also know that the adiponectin gene has the same location as one of the diabetes susceptibility genes on chromosome 3q27, and several longitudinal studies showed that human subjects with lower baseline adiponectin levels are more likely to develop type 2 diabetes, independent of adiposity. In contrast, type 1 diabetic patients may have elevated adiponectin levels compared to nondiabetic individuals, whereas chronically administered insulin does not have an effect on adiponectin levels.

Taken together, all these findings show that adiponectin levels are low in states of insulin resistance, such as obesity and type 2 diabetes, and adiponectin levels increase with improved insulin sensitivity after weight reduction or treatment with insulin-sensitizing drugs (thiazolidindiones). It is currently thought that adiponectin represents a link among obesity, insulin resistance, and various other metabolic abnormalities associated with obesity.

Adiponectin improves insulin sensitivity through multiple cellular and molecular mechanisms that are not entirely known at present. An important enzyme stimulated by adiponectin is AMP-activated protein kinase (AMPK), which, in turn, phosphorylates several intracellular proteins to alter various cellular functions, including the enhancement of insulin-stimulated glucose uptake into fat and skeletal muscle as well as the suppression of hepatic glucose production and stimulation of fatty acid oxidation. By

increasing fatty acid oxidation through AMPK activation, adiponectin decreases circulating free fatty acids, resulting thus in improved insulin action. Adiponectin may also improve insulin sensitivity by inducing the activation of the insulin signaling system. Moreover, by stimulating nitric oxide (NO) formation, adiponectin may augment vascular blood flow to promote glucose uptake.

In addition to its insulin-sensitizing effects, adiponectin is also related to the lipid profile, another independent risk factor for cardiovascular disease. Previous studies reported a strong positive association between adiponectin and high-density lipoprotein (HDL) cholesterol and a negative association with serum triglyceride levels. However, there is no independent relationship between adiponectin and low-density lipoprotein (LDL) or total cholesterol. Adiponectin may lead to a favorable lipid profile by stimulating fatty acid oxidation, an effect probably mediated by AMPK. However, one study reported increased fatty acid oxidation in muscle cells in adiponectin-knockout mice, and a cross-sectional study of humans found that plasma adiponectin levels did not correlate with lipid oxidation, as measured by energy expenditure and respiratory quotient. Thus, further studies are needed to understand adiponectin's effects on fatty acid oxidation.

Adiponectin may also exert important anti-inflammatory and atheroprotective effects. It inhibits the production and action of several inflammatory factors involved in atherosclerosis, including TNF- α , and also suppresses monocyte adhesion and macrophage transformation to foam cells within the vascular wall. In addition, adiponectin inhibits smooth muscle cell proliferation in the vascular wall by inhibiting growth factors that promote hyperplasia and promotes vasodilation and angiogenesis by increasing NO production in endothelial cells through AMPK activation. In conclusion, adiponectin's involvement in cardiovascular disease is probably multifactorial, including its effects on risk factors such as insulin resistance and dyslipidemia but also a direct effect on the vascular system.

Furthermore, there is emerging mechanistic and epidemiological evidence supporting a protective role of adiponectin in malignancies. *In vitro* treatment of acute myelomonocytic leukemia cell lines with adiponectin suppressed the growth of myelomonocyte cells, induced apoptosis, and downregulated *Bcl-2* gene expression. More recently, adiponectin has been shown to be a direct inhibitor of angiogenesis *in vivo* and *in vitro* through the activation of caspases in endothelial cells. Consistent with the *in vitro* studies, which suggest that adiponectin is an important negative regulator of hematopoiesis and the immune

system, *in vivo* intratumoral administration of murine adiponectin resulted in significant suppression of T241 fibrosarcoma tumor growth. Adiponectin receptors are expressed by prostate, hepatocellular carcinoma, and various other cancer cell types (breast, endometrial, colon, and neuroblastoma cell lines). Recent experiments suggest that adiponectin may act on tumor cells directly through the activation of c-jun NH₂-terminal kinase, a mammalian MAPK family involved in the regulation of cell proliferation and apoptosis, and also through the suppression of the transcription factor signal transducer and activator of transcription (STAT)3, which also regulates cell proliferation, differentiation, survival, and apoptosis. Therefore, given its antiangiogenesis properties and the inactivation of STAT3 reported in obesity and associated malignancies, adiponectin may prove to be an effective novel anticancer agent.

Epidemiological evidence also suggests that adiponectin plays an important role in the insulin-related pathways of carcinogenesis, independently of other known risk factors for cancers. We and others have recently reported that circulating adiponectin levels are inversely associated with risk for endometrial, breast, prostate, gastric, and colorectal cancer. In two recent case-control studies, we reported that women with high BMI and low plasma adiponectin had a 6.5-fold increased risk of endometrial cancer, independent of the possible effects of insulin-like growth factor (IGF)-1, IGF-2, IGF binding protein (IGFBP)-3, leptin, BMI, and other known risk factors of the disease. We also found in a prospective study in men that individuals in the highest quintile of adiponectin levels had an approximately 60% reduced risk for colorectal cancer compared to the lowest quintile. Significantly, these associations were also independent of body size and physical activity.

In addition, adiponectin levels may also correlate inversely with tumor size, histological grade, and disease stage in gastric and prostate cancer. Large association and prospective studies to prove adiponectin's role in the development of malignancies as well as mechanistic studies to address potential roles of adiponectin in cancer pathogenesis are needed.

Resistin

Resistin (adipose-tissue-specific secretory factor or FIZZ3) is a 94-amino-acid polypeptide with 11 cysteine residues. Resistin is almost entirely expressed and excreted from white adipose tissue in mice and circulates as a dimer. A single dicysteine residue is required for dimerization, whereas the remaining 10 cysteine residues are involved in determining the structure of the resistin monomeric unit.

Similar to adiponectin, resistin has been postulated to link obesity with insulin resistance, but these two molecules probably have opposite functions. In 2001, Steppan and colleagues reported that resistin secretion is decreased by the antidiabetic drug rosiglitazone and is increased in diet-induced and genetic mouse models of obesity. Moreover, the administration of antiresistin antibody improves blood sugar and insulin action in obese mice, and the administration of recombinant resistin impairs glucose tolerance and insulin action in normal mice. More recent studies have shown that resistin may increase hepatic insulin resistance by inhibiting AMPK and may also increase hepatic glucose production, thus controlling glucose and lipid metabolism. In addition, resistin has been postulated to regulate adipose tissue mass by inhibiting adipocyte differentiation and thus limit adipose tissue formation in response to increased energy intake. These observations have not been confirmed by other studies, however; thus, the role of resistin in mice remains controversial.

Human data are even more conflicting. Although resistin is expressed at very low levels in human adipose cells, high levels are expressed in circulating mononuclear leukocytes and macrophages. Similar to its distribution in rodents, resistin is found in human sera, and several studies (but not all) reported increased levels in obese and diabetic patients and a positive association with insulin resistance. One study showed that human resistin expression, but not serum levels, is proportional to insulin resistance, and several studies failed to show an association with insulin resistance. Resistin may have pro-inflammatory effects because recent *in vitro* studies found that resistin induces the expression of adhesion molecules such as vascular cell adhesion molecule (VCAM)-1 and intercellular adhesion molecule (ICAM)-1 in human endothelial cells.

Further studies are required to determine whether stress influences resistin levels and to elucidate the role of resistin in regulating insulin sensitivity. In addition, whether resistin influences obesity either directly or indirectly by altering glucose and insulin levels and whether resistin plays a role in inflammation associated with obesity warrant further investigation.

Gastrointestinal Tract: Ghrelin

Ghrelin, a 28-amino-acid lipophilic peptide with a labile octanoyl fatty acid side chain at the serine residue 3, was originally discovered by Kojima and coworkers during their search for an endogenous growth hormone secretagogue. This hormone is expressed primarily in specialized enterochromaffin cells (called X/A-like cells), which are located mainly

in the mucosa of the fundus of the stomach. In addition, ghrelin-immunoreactive cells are also found in the intestine, with their concentration gradually decreasing from duodenum to colon; they are also found in the pancreatic islets, brain, and kidney. Ghrelin-producing neurons are located in the hypothalamus, more specifically in the hypothalamic arcuate nucleus, an important region controlling appetite, but also in previously uncharacterized neurons adjacent to the third ventricle, which send efferent fibers to NPY and AgRP neurons, stimulating the release of these orexigenic peptides.

Ghrelin binds to the growth hormone secretagogue receptor (GHS-R), a typical G-protein-coupled receptor, the activation of which by ghrelin results in increased intracellular calcium via the activation of the phospholipase C pathway. GHS-Rs are expressed in various regions of the brain, predominantly in the growth hormone-releasing somatotroph cells of the pituitary gland. Ghrelin stimulates the release of growth hormone from the pituitary in a dose-dependent manner and acts synergistically with growth hormone-releasing hormone (GHRH). In addition, ghrelin has a weak prolactin (PRL) and ACTH-releasing activity, but more important ghrelin can modulate gonadotropin-releasing hormone (GnRH) pulses, possibly being one of the signals that turns off the gonadal axis during starvation. The expression of ghrelin in the pituitary is high after birth and declines with puberty.

In addition to being a potent growth hormone secretagogue, ghrelin is a potent appetite stimulant. Ghrelin administration by intracerebroventricular, intravenous, or subcutaneous injection increases food intake and body weight, decreases fat use, and increases gastric acid output in a dose-dependent manner. Administered to rats by intracerebroventricular injections, ghrelin induces Fos protein expression, a marker of neuronal activation, in regions of primary importance in the regulation of feeding, including NPY neurons and AgRP neurons, but also in the neurons of the solitary tract nucleus and the dorsomotor nucleus of vagus. The latter may sustain a role for ghrelin in the central regulation of gastric acid secretion and gastric motility via vagal cholinergic pathways.

Ghrelin circulates in the bloodstream in two forms, acylated and desacyl ghrelin, with the acylated form being the biologically active form of ghrelin. Serum levels of ghrelin depend on the state of nutrition and are negatively correlated with the BMI. Accordingly, circulating ghrelin levels are decreased in obesity but elevated during fasting and in anorexia nervosa and cachexia, a finding that may reflect a compensatory mechanism. Acute psychological stress raises plasma ghrelin in the rat, and the activation of gut sympathetic

nerves directly stimulate ghrelin secretion. Also, an increase in plasma ghrelin leads to the release of ACTH and the activation of the HPA axis. Recent human data demonstrated an inverse correlation between ghrelin and leptin that is independent of adiposity, but there is no regulation of ghrelin by leptin administration over the short term (a few hours to a few days).

In normal humans, plasma ghrelin levels rise immediately before each meal and in response to diet-induced weight loss and fall to minimum levels 1 h after feeding. This fall in ghrelin levels after a meal is correlated with insulin peak, suggesting that insulin may be a negative regulator of ghrelin secretion in the postprandial state. This fall in ghrelin levels after a meal is absent or blunted in obese humans, a fact that, researchers propose, may contribute to the development of their obesity. Significantly, obese patients who undergo gastric bypass surgery have significantly lowered ghrelin levels after surgery, which, on the basis of observational studies, has been proposed to contribute to maintaining decreased weight after bypass surgery.

Finally, what are potential clinical applications of ghrelin? It has been suggested that blocking or neutralizing ghrelin action may prove to be a reasonable pharmacological approach to reverse a chronically positive energy balance, such as in obesity. However, in contrast to predictions made from the pharmacology of ghrelin, studies in ghrelin-null mice showed that the deletion of ghrelin impairs neither growth nor appetite. In fact, ghrelin-null mice are neither anorexic nor dwarfs and display normal responses to starvation and diet-induced obesity, strongly suggesting that ghrelin is not critically required for viability, fertility, growth, appetite, or fat deposition. Thus, antagonists of ghrelin may not prove to be very successful anti-obesity agents. In contrast, exploring its orexigenic activity for the treatment of eating disorders such as anorexia nervosa or the replacement of ghrelin in ghrelin-deficient states such as cachexia or other catabolic states seems to be a more reasonable approach.

Conclusion

This brief review has covered recent advances in the area of molecules regulating energy homeostasis

and metabolism – leptin, adiponectin, resistin, and ghrelin. Most probably, we can expect other related hormones to be added to this list in the near future. In addition, synthetic analogs, agonists, or antagonists are expected to be developed by the pharmaceutical industry for the management of states of energy excess, such as obesity and type 2 diabetes, and states of energy deficiency, such as anorexia nervosa and hypothalamic amenorrhea.

Introduction

What Is Leukocyte Trafficking?

Acute Stress Paradigms

Chronic Stress Paradigms

Underlying Mechanisms and Mediators

Potential Clinical Implications

Summary

Glossary

Cellular adhesion molecules (CAMs)

Cell surface molecules that mediate leukocyte migration, homing, and cell-to-cell interaction. Types of adhesion molecules are the integrins, selectins, cadherins, and proteins of the immunoglobulin superfamily.

Cluster of differentiation (CD)

A uniform nomenclature system developed for distinguishing lineage or differentiation stage of leukocytes by identifying surface proteins that are recognized by a group of monoclonal antibodies.

Cytokines

Soluble proteins produced mostly by activated immune cells during effector phases. They regulate and mediate immune and inflammatory responses.

Enzyme-linked immunosorbent assay (ELISA)
Flow cytometry

A serological assay that detects the concentration of bound antigen or antibody through a photometer.

A cellular research tool to characterize individual cells or other microparticles by size, granularity, and surface or intracellular markers using fluorescent-labeled antibodies.

Granulocytes

A subset of leukocytes that originate in the bone marrow and include neutrophils, eosinophils, basophils, and mast cells that possess abundant cytoplasmic granules. About 90% of the peripheral blood cells are granulocytes.

Inflammation

Process that begins with cytokines produced by activated immune cells upon recognition of the antigen presence.

Leukocytosis

An increase of leukocyte (white blood cells) numbers in the peripheral circulation.

Lymphocytes

A subset of leukocytes, including natural killer (NK), T, and B cells, that are major mediators of adaptive (specific) immunity in mammals. They originate in the bone marrow.

Monocytes

A subset of leukocytes that mature to become macrophages and that are phagocytic and produce cytokines.

Introduction

The immune system is the body's defense against disease-causing agents. It is complex yet well orchestrated and nearly self-regulatory. It provides surveillance throughout the body via circulation of white

blood cells. The circulation of immune cells is an ongoing process under normal conditions (e.g., no infection), but the trafficking pattern changes under pathogenic conditions to accommodate the mounting of an immune response.

It is of great interest to researchers that there are other stimuli (that are not immunogenic) that lead to changes in trafficking of immune cells; one of these stimuli is stress. Stressors are acute immune system activators that lead not only to modulation in immune functions but also to leukocyte influx into the circulation. The effects of acute stress on leukocyte trafficking are mostly transient and fairly well understood, but the possible lasting effects of chronic stress on leukocyte mobilization are still largely unknown. While decades of research has helped delineated the effects of stress on leukocyte populations, it is only recently that the mechanisms underlying the phenomenon are being revealed, including various neurohormones and their respective receptors and cellular adhesion molecules.

This article reviews what is currently known about the effects of acute and chronic stressors on leukocyte trafficking, including discussion of mechanisms and potential clinical implications. It focuses on the evidence of changes in circulating leukocytes rather than in other tissues or lymphoid organs. The terms traf-

ficking, demargination, leukocytosis, and mobilization are used interchangeably.

What Is Leukocyte Trafficking?

Surveillance and Inflammation

Even though only 2% of total leukocytes are in the peripheral circulation at any given time, they provide a diagnostic account of the functional status of the immune system. The majority are homed in lymphoid organs and the rest are diffusely distributed in other organs. During infection or injury migration of immune cells to different sites of antigen localization within the body is critical to host defense. Recognition of antigen leads to cytokine production, causing inflammation in the area that facilitates recruitment of circulating leukocytes to the infected site. Many of the mechanisms responsible for regulating these types of fundamental responses of the immune system, including cellular adhesion molecules (CAMs), are also central to the regulation of the immune response to stressors.

Major Players: Cellular Adhesion Molecules

Initial trafficking, rolling, and firm adhesion of leukocytes to sites of inflammation are mediated by cytokines and CAMs (e.g., L-selectin, LFA-1, VLA-4, and CD44), which are homing receptors on the immune cells, and their ligands on endothelial cells (molecules that binds to a macromolecule, such as

Figure 1 Schematic diagram of stages in migration and adhesion of leukocytes and cell adhesion molecules. (I, II) Stimulating factors including pro-inflammatory cytokines result in activation of leukocytes and endothelial cells and lead to increased expression and activation of adhesion molecules on both endothelial and immune cells. (III) Selectins (e.g., L-selectin) bind to ligands on the endothelium (e.g., GlyCAM-1), causing leukocytes to be captured, roll, and tether. (IV) Activation and binding of integrins (e.g., LFA-1) to ligands (e.g., ICAM-1) leads to attachment and further activation of leukocytes. (V) Leukocytes transmigrate through the endothelial wall.

a receptor, e.g., E-selectin, GlyCAM-1, ICAM-1, and VCAM-1). Inflammatory stimuli (e.g., cytokines tumor necrosis factor- α [TNF- α] and interleukin-1 [IL-1] and chemokines [chemotactic cytokines]) and antigen recognition by immune cells lead to the expression of these molecules on both immune cells and endothelial cells. Leukocytes then attach to endothelial cells lining the infected areas (firm adhesion) and penetrate into the tissue (transmigration).

Adhesion of leukocytes to the endothelium involves multiple processes. First, the initial contact of leukocytes to the endothelium is mediated by L-selectin (CD62L), tethering them loosely to carbohydrate ligands like GlyCAM-1 as they roll along the surface, as shown in [Figure 1](#). Until the leukocyte gets activated, this rolling process is reversible. Second, during activation, chemokines are released by the endothelium and trigger integrin LFA-1 (CD11a) expression on the leukocyte surface to bind tightly to the intercellular adhesion molecule ICAM-1 (CD54) on the endothelium. This event leads to an eventual transendothelial migration (extravasation). CAMs, such as L-selectin and ICAMs, are shed in a soluble form during the process and can further participate in biological processes. As mentioned previously, cytokines play a crucial role in trafficking and homing of leukocytes: inflammatory conditions, which activate macrophages and monocytes to release cytokines such as TNF- α , further activate the endothelium. This leads to upregulation of endothelial adhesion molecules, such as ICAM-1 and the vascular VCAM-1, which further attract leukocytes. Other cytokines, such as IL-2, IL-4, and IL-10, are suggested to have inhibitory effects through reduction of CAMs. The expression of CAMs is assessed by quantifying adhesion molecules on the surface of circulating leukocytes (using flow cytometry) and by determining the levels of their circulating soluble form (typically by enzyme-linked immunosorbent assay [ELISA]).

Acute Stress Paradigms

Numerous studies demonstrate that the immune system is responsive to acute psychological events. One example of immune reactivity to stress is the increased numbers of leukocytes in circulation. Evidence for this dates back to the 1930s, when Farris described the relationship among emotional stress, academic exams, and increases in the number of circulating leukocytes. A relatively parallel phenomenon in response to acute physical stress has also been documented. During the past two decades, with the more sophisticated research tools and techniques available, investigators have been actively examining the

nuances of these phenomena, as well as researching the mechanisms that regulate them.

Psychological Stress

Researchers have used a wide variety of naturalistic and standardized stressors to investigate the phenomenon of acute psychological stress-induced leukocytosis. These stress paradigms include mental and emotional stressors such as uncontrollable stimuli (e.g., shock and noise), laboratory stressors (e.g., the color-word Stroop test and mental arithmetic test), and real-life stressors (e.g., academic examinations, piloting airplanes, giving a public speech, and parachute jumping). Regardless of the stress model used, psychological stress leads to leukocytosis at varying degrees depending on the type and duration of the stressor. The literature, for example, shows marked increases in the circulation of natural killer (NK) and CD8⁺ T cell subsets, a decrease in the CD4⁺/CD8⁺ ratio, and small increases in helper T and B cells. Bosch and colleagues recently reported that a subset of NK cells is more responsive to a speech stressor such that the number of NK cells expressing low levels of CD56 (cytotoxic) tripled but the number of NK cells expressing high levels of CD56 (regulatory) did not change following a stressor. Together, such findings have raised several questions, including why selected subsets of leukocytes are more responsive to stress, and from which sites the leukocytes are being released? Regarding the first question, studies suggest that it is in part attributable to a different degree or profile of CAM expression and receptors for neurotransmitters and stress hormones on different cell types. Regarding the second question, immune cells are released from the so-called marginal pools as well as from the spleen, which is a primary reservoir of circulating leukocytes, especially following sympathetic nervous system activation.

Psychological stress also leads to changes in CAM expression on peripheral (demarginated) leukocytes. It is consistently shown that the phenomenon of leukocyte redistribution in response to acute stress can be differentiated according to L-selectin (CD62L) expression. As seen in [Figure 1](#), L-selectin serves a crucial role in a leukocyte's initial rolling on the endothelium. Findings suggest that it is primarily lymphocytes not expressing L-selectin (CD62L⁻) that markedly increase in the circulation following acute stress (either psychological or physical). CD8⁺CD62L⁻ T cells, for example, show a two- to threefold increase in the circulation following acute stress as compared to CD8⁺CD62L⁺ T cells, which show either no change or a more moderate increase. A similar CD62L^{-/+} response differentiation is shown

for both CD4⁺ and NK lymphocytes. This phenomenon most likely results from a combination of events, including a preferential release of CD62L⁻ lymphocytes from the spleen and marginal pools, an increased rate of adhesion of CD62L⁺ lymphocytes, and a downregulation or shedding of CD62L from the leukocyte's surface upon further activation.

Physical Stress

In addition to the phenomenon of psychological stress-induced leukocytosis, researchers report dramatic increases of immune cells in the circulation after a bout of exercise. It should be made clear here that a bout of exercise should be distinguished from longitudinal exercise training (see Physical Stress Models and Adaptation below). And, in this article, acute exercise is discussed as a physiological stressor, given the cardiopulmonary, metabolic, and hemodynamic demands of exercise on the individual. In addition, a large body of literature on the effects of exercise on the neuroendocrine system supports the notion that exercise is a biologically plausible paradigm to investigate stress-induced modulation of the immune system.

Changes in circulating cell numbers in response to exercise vary among subpopulations of leukocytes and are dependent upon the intensity and duration of the exercise challenge. There is a dose response in exercise-induced leukocytosis such that mild exercise results in smaller changes in cell numbers. Marked increases in numbers of most lymphocyte subsets, monocytes, and granulocytes are consistently observed. Similar to psychological stress, small or no changes are typically seen in numbers of B lymphocytes, even after exercise of a moderate to high intensity. Changes in NK cell and neutrophil numbers after exercise are most dramatic; the number of NK cells can increase two- to fourfold above resting levels. Interestingly, a small subset of monocytes that also expresses CD16 (CD14⁺CD16⁺) (CD16 is largely expressed on NK cells) is shown to be mobilized to the circulation during exercise at a larger degree than regular monocytes (CD14⁺CD16⁻). Not only cardiovascular exercise but also resistance exercise using relatively small muscle groups can significantly affect circulating immune cells.

In spite of the consistent findings on associations between exercise intensity and leukocytosis, exhaustive and prolonged exercise (e.g., a marathon or triathlon) results in decreased immune cell numbers (leukocytopenia; especially T and NK cells) in the circulation. Although the reason for this trafficking pattern after prolonged exercise is unclear, there are several possible explanations. It may well be that the initial leukocytosis for the first 20–30 min of a marathon may be followed by a gradual decline,

resulting in leukocytopenia as the high-intensity exercise continues. As is discussed later, sustained activation of the hypothalamic-pituitary-adrenocortical (HPA) axis, resulting in high cortisol levels, may be a mediating factor for decreased immune cell numbers after a marathon. In addition, muscular tissue injury during a marathon or triathlon may also be a contributing factor, although whether the leukocytopenia seen after a marathon reflects the redistribution of the cells to the fatigued or damaged muscle tissue is not known.

During exercise, leukocytes may demarginate to the peripheral blood compartment in part by increased hemodynamic forces that detach cells that normally loosely adhere to the vessel walls at rest. Cells that are mobilized into the circulation during exercise appear to be from the secondary lymphoid organs (the spleen and lymph nodes) rather than the primary lymphoid organs (the thymus and bone marrow), given findings that a greater percentage of activated CD62L⁻ memory T cells demarginate as compared to naive cells. Thus, exercise-induced leukocytosis appears to be a redistribution of cells from the spleen and lymph nodes rather than proliferation or differentiation of them from primary sources.

As with the psychological stress responses, CD62L⁻ lymphocytes appear highly responsive to an acute exercise challenge. Granulocytes and lymphocytes show a significant decrease in the surface density of CD62L following exercise. A similar shedding process may also occur with the adhesion molecule ICAM-1. Such a shedding of ICAM-1 might lead to a further demargination of CD62L⁻ leukocytes back into the circulation. Studies demonstrate an increase in levels of soluble ICAM-1 following exercise, supporting such a conjecture.

Pharmacological Stress

In order to test the hypothesis that leukocytosis following psychological or physical stressors may be mediated by sympathetic nervous system activation, investigators have examined leukocyte trafficking by administering sympathetic (adrenergic) agonists. Pharmacological infusion studies of such agonists provide direct mechanistic evidence for the stress-leukocytosis phenomenon. Infusion of the nonspecific β -adrenergic agonist isoproterenol (a pharmacological agent that leads to similar physiological effects as norepinephrine), for example, leads to increases in CD8⁺ T and NK cell numbers in blood. Isoproterenol also leads to increased numbers of CD62L⁻ but not CD62L⁺ CD8⁺ cells as well as a decrease of CD62L density and increased CD11a density. Activated/memory T cells appear more responsive to the infu-

sion as compared to naive T lymphocytes. Studies using β -adrenergic antagonists such as propranolol to block sympathetic agonist effects in combination with stressors provide further evidence of adrenergic regulation of leukocytosis. Ingestion of propranolol for 5 days leads to a blunted stress-induced lymphocytosis to psychological and exercise stressors. For example, the $CD8^+CD62L^-$ T cell response to exercise is dramatically attenuated by treatment with propranolol. Together, these findings indicate that acute stress-induced leukocyte trafficking is mediated in part by β -adrenergic receptor activation.

Chronic Stress Paradigms

Psychological Stress

It is widely believed that more enduring stressors lead to downregulation of immune function and increased disease susceptibility. Studies report immune suppression under such chronic stressors as marital strife, bereavement, long-term caregiving, living in an unfavorable environment such as near a nuclear power plant, and environmental disasters such as floods and hurricanes. Immunosuppressive effects of chronic stress include a decrease in circulating leukocyte NK cell number and activity at rest, a lower cytokine release rate, and enhanced antibody titer for latent viruses such as herpes simplex virus type 1 and Epstein-Barr virus. Kiecolt-Glaser et al. reported that medical students who experience high stress levels and poorer social support during academic examination exhibit very low NK cell activity.

As with acute stress studies, CAMs appear to have an important role in mediating the effects of chronic stress on leukocytes. For example, one study was conducted on CD62L expression on T lymphocytes among elderly (average age of 75 years) spousal caregivers of Alzheimer patients experiencing high stress levels due to increased caregiving burden, who were compared to a group of caregivers with a relatively low stress burden from caregiving. The highly stressed caregivers showed significantly lower numbers of circulating $CD8^+CD62L^-$ and $CD4^+CD62L^-$ T cells at rest and during acute psychological stress but no differences in $CD62L^+$ T cells as compared to the control group. Lower numbers of $CD62L^-$ T cells in the circulation indicate that there is decreased availability of activated/memory T cells. In addition, this deficit in activated/memory T lymphocytes, cells that are critical in mounting immune responses, may imply a stress-associated accelerated decline of immunity in these older individuals, which, in turn, might have adverse consequences for health.

Physical Stress Models and Adaptation

It is of great interest to many researchers to determine if chronic exercise training or regular physical activity leads to a favorable modulation of the immune system. Contrary to findings of immunosuppression and potential increased disease susceptibility following chronic psychological stress, long-term regular exercise typically leads to improvements in health. It is unclear, though, whether regular exercise leads to enhanced immunity or changes in immune cell distribution that would support observations of improved health. In general, findings on the effects of chronic exercise (training) or physical fitness on resting peripheral blood leukocyte numbers and adhesion molecule expression are inconclusive, with no consistent effects shown for $CD4^+$, $CD8^+$, or B lymphocyte numbers among studies.

However, physical fitness might affect leukocyte trafficking in response to acute stressors. It has been shown that physically fit individuals exhibit attenuated lymphocytosis in response to a speech stressor and to a moderate exercise challenge (Figure 2). This blunted response to a stressor is not derived from the differences in cell numbers at rest and is only observed among T lymphocytes, not in monocytes, granulocytes, or NK cells. In addition, a significant attenuation of demargination is found for $CD4^+$ memory T cells that do not express the activation marker HLA-DR after exercise in fit individuals. Such findings imply that the effects of fitness on leukocytosis is cell type and activation stage specific.

Underlying Mechanisms and Mediators

How do stress-induced changes in leukocyte trafficking occur? How is selective and cell type-dependent mobilization explained? What factors influence CAM expression during leukocyte trafficking? There are two main underlying physiological pathways that address these questions.

Sympathetic Nervous System Activation

There is widespread direct communication between the sympathetic nervous system (SNS) and the immune system. Adrenergic projections and sympathetic nerve terminals are found in many organs of the immune system, including the spleen. Sympathetic agonists (catecholamines) are rapidly released from nerve endings following acute SNS activation and act directly on α - and β -adrenergic receptors. β_2 -adrenergic receptors are found on all white blood cells, including lymphocytes, neutrophils, and monocytes. Activation of these receptors leads to lymphocytosis. Adherence

Figure 2 Naive and memory $CD4^+$ and $CD8^+$ T lymphocyte numbers pre-, post-, and 10-min postexercise in high- vs. low-fitness groups. Physically fit subjects showed reduced $CD4^+$ and memory $CD4^+$ T cell responses (indicated by *) but not in naive $CD4^+$ T cell responses. Fit subjects showed smaller $CD8^+$ naive and memory cell responses. LF, low fitness; HF, high fitness; pr, pre-exercise; p, postexercise; r, recovery; * and ** denote significant ($p < 0.05$ and $p < 0.01$, respectively) time by group interactions (mean $\pm$ standard error).

of NK cells to endothelial cells is decreased in a dose-dependent manner after adding β_2 -adrenergic agonists *in vitro*. As described previously, infusing the β -adrenergic agonist isoproterenol leads to demargination and trafficking of leukocyte subsets similar to those seen following a stressor. Catecholamines lead to increased recirculation of lymphocytes into the blood by decreasing the affinity of the lymphocyte to the vessel wall, and possibly through a shedding of adhesion molecules such as CD62L and ICAM-1 from the cell surface.

The HPA Axis

Neuroendocrine responses to stressors include increased levels of glucocorticoids in circulation as a result of HPA activation. Glucocorticoids are known for their immunosuppressive effects. Their pharmacological administration has wide-ranging effects, including the modulation of metabolic processes and immunosuppression. Glucocorticoids are widely used in the treatment of many inflammatory conditions, influencing the migration of immune cells to infected tissues. Studies demonstrate that glucocorticoids reduce the number of circulating leukocytes and down-regulate cytokine production and chemotaxis, as well as downregulate adhesion molecules such as E-selectin

and ICAM-1. *In vivo* studies demonstrate time-related effects of dexamethasone on ICAM-I expression, in which prolonged treatment (but not single acute doses) significantly reduces ICAM-1 expression on monocytes.

Mediators

As with many other physiological processes, inter-individual factors such as age, diet, gender, ethnicity, and psychosocial characteristics can affect leukocyte trafficking in response to stressors. Depression, lack of social support, or hostile personality, for example, can all lead to altered immune cell responses to acute stress. Although studies examining the effects of gender as a possible mediator of leukocyte trafficking during stressors have been inconsistent, studies examining the effects of reproductive hormones do indicate an effect. A low- versus a high-carbohydrate meal leads to attenuated leukocyte and neutrophil trafficking in response to exercise. Although aging appears to be associated with a general decline in immune function, including a loss of naive T lymphocytes, few studies have systematically investigated whether age influences stress-induced leukocyte trafficking. As discussed earlier, physical fitness is a very important mediator of leukocyte responses to both exercise and psychological stressors.

Figure 3 The effects of hypertension on the leukocyte-endothelial adhesion response to exercise. Percentage change of peripheral blood mononuclear cell (PBMC) adhesion to human umbilical venous endothelial cells (HUVEC) under control and cytokine-stimulated conditions at rest and in response to acute exercise in hypertensive patients and normotensive subjects. In response to exercise, PBMC adhesion to HUVECs was increased in hypertensives but decreased in normotensives under control and stimulated conditions ($p < 0.03$). Reprinted from Mills PJ, Maisel AS, Ziegler MG, et al. 2000. Peripheral blood mononuclear cell-endothelial adhesion in human hypertension following exercise, *Journal of Hypertension*. 18(12), 1804 with permission from the publisher.

Potential Clinical Implications

Are there potential clinical implications associated with exaggerated or perhaps diminished leukocyte trafficking responses to stressors? A few studies have endeavored to address this issue by studying clinical populations. For example, hypertension, or high blood pressure, is a well-established risk factor for atherosclerosis, which is an inflammatory disease. Patients with hypertension have elevated endothelial expression of the adhesion molecules ICAM-1, VCAM-1, E-selectin, and P-selectin. This enhanced CAM activation attracts leukocytes and monocytes to adhere to the endothelial surface, supporting inflammation. As previously discussed, the SNS plays a prominent role in leukocyte trafficking and CAM expression. Elevated sympathetic nerve activity and circulating catecholamines levels are common in hypertension. It is reasonable, therefore, to hypothesize that the sympathetic mediation of leukocyte trafficking and cell adhesion may be accentuated in hypertension. Incidentally, in addition to direct SNS activation effects, greater hemodynamic forces found in hypertension also contribute to the phenomenon of endothelial activation and increased expression of endothelial CAMs.

Findings show a greater expression of LFA-1 (CD11a) on circulating lymphocytes at rest and in response to stressors in hypertensive patients. In addition, the adhesion of lymphocytes to endothelial cells in hypertensives is enhanced in response to the stressor of exercise but reduced in people with normal blood pressure (Figure 3). Such differences in the adhesion characteristics of lymphocytes in hypertensives following stress might have clinical relevance, as adherent mononuclear cells mediate endothelial injury associated with atherosclerosis as well as with ischemic disorders. However, whether such stressor-related effects on leukocytes are related to the etiology and/or progression of vessel disease in hypertension has yet to be demonstrated. More research is needed on the possible clinical relevance of stress-induced changes of immune cell adhesion before the significance of such observations can be fully understood. Stress-induced leukocyte trafficking also merits further investigation of its clinical implications in other clinical populations, including patients with cancer, multiple sclerosis, and rheumatoid arthritis.

Summary

Circulation of immune cells throughout the body is a critical immunosurveillance process for host defense. Many studies demonstrate mobilization of immune

cells in response to acute and chronic psychological and physical stressors. Stress-induced leukocytosis is cell subset specific and there is a dose response based on the intensity of the stressor. CAMs, including CD62L, CD11a, and ICAM-1, play a crucial role in the phenomenon. Both the SNS and the HPA axis help regulate immune cell responses to a variety of stressors. Numerous important questions still need to be answered, including the identity of interindividual factors that significantly mediate immune cell responses to stressors, as well as the potential clinical implications of this interesting effect of stressors on the trafficking of immune cells in the blood.

Annual prevalence

Life event

Major depressive disorder

The proportion of people identified with a disease or other characteristic at any time during the period of a year.

A discrete incident or circumstance that may disrupt life, may require adaptation, and may be associated with, or result in, physical and/or emotional health change. A health state characterized by sustained feelings of sadness, hopelessness, helplessness, and worthlessness that is often also accompanied by suicidal thoughts, an inability to concentrate or to take pleasure in activities that were once enjoyable, and sleep, appetite, and memory problems.

Measurement

Health Associations

Individual Differences

Glossary

<i>Annual prevalence</i>	The proportion of people identified with a disease or other characteristic at any time during the period of a year.
<i>Life event</i>	A discrete incident or circumstance that may disrupt life, may require adaptation, and may be associated with, or result in, physical and/or emotional health change.
<i>Major depressive disorder</i>	A health state characterized by sustained feelings of sadness, hopelessness, helplessness, and worthlessness that is often also accompanied by suicidal thoughts, an inability to concentrate or to take pleasure in activities that were once enjoyable, and sleep, appetite, and memory problems.
<i>Prospective cohort study</i>	A study population defined according to risk factor exposure and prospectively followed up, for example, to ascertain incident disease endpoints.
<i>Record linkage study</i>	A study that brings together information included in two or more records based upon a unique identifying system.

On January 17, 1995, at 5:46:52 a.m., the southern part of Hyogo Prefecture in Japan was struck, without warning, by the Hanshin-Awaji earthquake, which measured 7.2 on the Richter scale and lasted for around 20 s. During the 3 months following this unexpected catastrophic natural disaster, in the districts of Awaji Island near the earthquake epicenter, heart attack rates increased by 50% and stroke rates by 90% in comparison with the same observation period during the previous year. Survivors in areas with the greatest loss and destruction of housing experienced the highest subsequent heart attack rates. While the occurrence of a profoundly stressful life event, such as the Hanshin-Awaji earthquake, provides a clear and dramatic incident from which to assess subsequent health, the attribution of health change to life events experienced more commonly across a lifetime is less straightforward.

Measurement

Life event assessment techniques have evolved to include the use of checklists and interview methods and have been used in a wide variety of research designs to aid understanding of the risk of life events to health.

Checklists

During the late 1940s, Thomas Holmes and colleagues at the University of Washington started to investigate the relationship between adjustment to social stress and illness onset using a self-administered

instrument, the Schedule of Recent Experience (SRE). The SRE included a list of 43 life change events intended to represent most circumstances experienced by the patient groups studied, and to which differing degrees of readjustment were required. A subsequent scaling study was designed to take account of both the intensity and the relative time judged to be needed to adjust to each life event on the list. This Social Readjustment Rating Scale (SRRS) included the life events ranked according to these degrees of readjustment – subsequently termed life change units (LCUs). The event of highest rank was death of spouse (with a mean value score of 100), relative to marriage, with a mean value score of 50, and, for example, death of close friend, which scored 37. Typically the LCUs for all events reported on the checklist to have been experienced during a given time period (e.g., the past year) were summed to give a measure of the cumulative social stress experienced. With varying degrees of modification, the SRRS has served as a model of a questionnaire format for assessing life event experience in relation to health. For example, in psychiatry, scaling studies focused on the capacity of life events to induce distress and were scaled in terms of their associated upset or undesirability. While the checklist approach provided a powerful impetus to study the association between life events and illness, these techniques attracted criticism. This stemmed from suggestions that the circumstances to be rated were defined vaguely, resulting in variability in item interpretation, that symptoms were included in the event lists, and that the assumption of additivity of event effects was untested. Despite these criticisms, the list techniques can provide a reliable assessment of the occurrence of specified adverse experiences, although they may be limited in their capacity to provide details of the context surrounding their occurrence.

Interviews

The Life Events and Difficulties Schedule (LEDS), an interview method for the assessment of stressful life events, was developed in the late 1960s and over the subsequent 30 years by George Brown and colleagues at London University. In contrast to the early respondent-based checklist assessment techniques, this approach was based on using the interviewer as the measuring instrument. Through the LEDS, ratings of adverse experience followed from consideration of both the context and meaning of the immediate circumstances associated with a stressful situation. Use of the LEDS was designed to provide measures of the long-term threat of life events experienced, to attempt to date their occurrence accurately, and

to rate ongoing long-term difficulties. In addition, LEDS-based research drew attention to the importance of distinguishing the extent to which life events and long-term difficulties could be illness-related in order to help clarify their etiological significance for illness onset.

However, Bruce Dohrenwend and colleagues, at Columbia University, New York, raised fundamental criticisms of the LEDS core ratings of contextual threat. These criticisms were based upon their view that the contextual ratings represented a nonexplicit distillation of the event, the social circumstances surrounding its occurrence, and the personal history of the person who experienced the event, into one measure. Dohrenwend and colleagues argued that these situational and personal variables may themselves be important risk factors for illness, therefore creating ambiguity in understanding precisely which aspects of the stress process were associated with the illness outcomes of interest. They attempted to address these perceived problems with the LEDS approach through developing their own theoretical framework and measurement approach, using the Structured Event Probe and Narrative Rating method (SEPRATE) of life events measurement. The SEPRATE semistructured interview method was designed to provide measures that distinguished between the life event, the ongoing social situation present before event occurrence (for example, employment circumstances), and the personal dispositions and characteristics of the person who had experienced the life event. While the LEDS and SEPRATE share similarities in methodological approach, they differ markedly in their representation and rating of life event experience.

Health Associations

Efforts to synthesize research findings relating life events to health outcomes have been limited by the rarity of studies that meet stringent research design requirements. A commonly used set of criteria to help establish causality was proposed by the epidemiologist and statistician Sir Austin Bradford Hill. These criteria include consideration of the strength of the association, whether it is consistent (i.e., repeatedly demonstrated in different populations), whether there is evidence of temporality (i.e., the presence of the risk factor precedes onset of disease), and whether a dose-response relationship exists (i.e., disease risk increases monotonically with increasing exposure). These criteria have not yet been fully met for any health outcome following from stressful life event experience. However, increasingly persuasive evidence

is now accumulating in relation to the onset, and subsequent prognosis, of some health outcomes.

Life Events and Psychological Health

Evidence from both prospective cohort and record linkage studies has consistently shown an association between the experience of stressful life events and the subsequent onset of episodes of major depressive disorder. The strength of this association has been shown to vary according to the way in which life events were assessed: generally stronger associations were reported when events were assessed using the LEDS approach, rather than through use of the list techniques such as the SRE. These studies have also suggested evidence of a dose–response relationship, with the risk of depressive disorder onset increasing broadly in step with the severity of the events experienced. A dose–response association between the number of recently reported stressful life events and the annual prevalence of depressive disorder is illustrated in [Figure 1](#).

Record linkage studies, through their use of very large populations, provide a potentially powerful research design with which to investigate the relationship between severely stressful events and psychiatric health. For example, one study linked records from the Danish Civil Registration System with the Danish Psychiatric Central Register to investigate the association between death of a child and subsequent

parental admission to psychiatric hospital. Based on over a million persons identified in the registers and almost 12 000 deaths of children aged under 18 years, the study revealed a 67% increased risk of hospital admission for any psychiatric condition among the parents who had lost a child, with the risk being greatest for mothers and most pronounced for admission with a depressive condition.

The relationship between chronic enduring or progressively deteriorating stressful circumstances and psychiatric health is complex and difficult to study. For example, changes in the Japanese economy during the late 1980s, subsequently associated with escalating bankruptcy rates, has been interpreted as a significant contributory cause of increases in the male suicide rate, stemming from the high proportion of suicide notes in which economic circumstances were the stated reason for suicide. The Japanese male suicide rate increased from around 25 per 100 000 during the mid 1990s to over 35 per 100 000 at the beginning of the twenty-first century, when over 30 000 Japanese per year committed suicide, by then around twice the rate observed in the United States.

Life Events and Physical Health

Clinicians have long suspected stressful life events to be associated with the onset of physical disease (for example, this was noted by Sir James Paget, the surgeon and pathologist, in his *Clinical Lectures and Essays* in 1875). The assessment of stressful life event experience within chronic disease epidemiological study settings presents substantial methodological challenges related to cost, the need to limit participant burden, and the requirement of asking perhaps tens of thousands of study participants, ideally when they are all healthy, to recall their experience of stressful events over a particular time period. In consequence, within large-scale prospective cohort studies, the assessment of stressful life events has been largely restricted either to the use of short event lists or to specific events (e.g., bereavement). Record linkage research designs have investigated the risk of chronic disease and mortality associated with specific stressful events; for example, following the death or serious illness of a child or loss of a partner or twin. Both prospective cohort and record linkage studies have now provided evidence that under some circumstances such events may increase risk for congenital malformations, heart disease, and perhaps some cancers, just a few among many physical health outcomes studied.

Figure 1 Annual prevalence of major depressive disorder according to the number of moderately or extremely upsetting (non-health-related) life events reported during the previous 5 years. Based upon 20 921 participants in the European Prospective Investigation into Cancer (EPIC)-Norfolk study in the United Kingdom.

Heart disease Sudden and particularly catastrophic life events, such as the 1995 Hanshin-Awaji

earthquake in Japan, the 1999 Ji-Ji earthquake in Taiwan, and the terrorist attacks on the World Trade Center in New York on September 11, 2001, have been associated with transient increases in blood pressure, increases in ventricular arrhythmias among patients with cardioverter defibrillators, and increases in the incidence of fatal and nonfatal cardiovascular events. Further, use of national registers in Denmark has shown that experiencing the unexpected death of a child (under 18 years) is associated with an increased subsequent risk of a heart attack (myocardial infarction) in the bereaved parents. The association between chronic stressful circumstances and cardiovascular events is less certain, but there is an increasing international consensus that a combination of high work demands and low job control is associated with cardiovascular events in certain occupational groups and that caregiving responsibilities for a disabled or ill partner for 9 or more h per week is associated with an increased risk of incident heart disease events in women.

Cancer Studies meeting stringent research design criteria that have been devoted to evaluating life events as possible determinants of cancer incidence and progression are rare. Evidence for the association between life events and cancer incidence is often contradictory, based on studies that often rely on imprecise case ascertainment methods, may be prone to recall bias in their assessment of life event histories, are able to include relatively few participants that develop cancer, and may be unable to include adjustment for factors known to be associated with cancer outcomes. Some of these limitations were overcome in a prospective study of a twin cohort of 10 808 women in Finland. During 15 years of follow-up, 180 incident breast cancers were diagnosed, and the results suggested that life events experienced during the 5 years before entry into the study were associated with an increased risk of breast cancer during follow-up. Three specific life events were found to be associated with an increase in breast cancer risk: divorce or separation, death of a husband, and death of a close relative or friend. The association between widowhood and divorce and subsequent cancer risk compared to married people has been investigated in a large Swedish study. A relatively consistent pattern of cancer risk was found in the divorced compared to the widowed (both with increases and decreases in risk, according to cancer site) that collectively may reflect changes in lifestyle following partner loss. Similar conclusions have been suggested to account for the evidence from record linkage studies that have found a slightly elevated overall cancer risk in mothers following death of a child.

Individual Differences

There are profound individual differences in the health consequences of stressful life events and difficult circumstances. These differences are most evident through studies of the health outcomes of people subsequent to their exposure to very stressful circumstances, including shipwreck, concentration camp experience, and terrorist attacks. Some people adapt to stressful circumstances more successfully than others. Not all people exposed to adverse or even traumatic circumstance experience health change. Identification of what distinguishes people in the way they are able to manage stressful life events can aid understanding of disease susceptibility and inform the design and delivery of effective care to reduce the long-term health impact of events. For example, a brief questionnaire designed to distinguish the extent to which people are optimistic about their lives and future expectations has shown that optimists have a reduced risk from dying due to cardiovascular causes over a 15-year period and after consideration of traditional risk factors. More direct evidence of individual differences in the capacity to adapt to stressful life events has followed from work originally inspired by Aaron Antonovsky's study of survivors of the Holocaust. This work has revealed how, despite their horrific experiences, some Holocaust survivors had subsequently been able to rebuild their lives successfully. Antonovsky defined sense of coherence (SOC), a theoretical construct based upon these observations, as a flexible and adaptive dispositional orientation enabling successful coping with adverse

Figure 2 Mean reported adaptation to death of spouse or partner according to the elapsed time since the event occurred and according to sense of coherence (SOC). Based upon 20 921 participants in the European Prospective Investigation into Cancer (EPIC)-Norfolk study in the United Kingdom. Mean adaptation score was calculated from responses to the question "Do you feel that you have got over this now?" (1 = completely, 2 = mostly, 3 = a little, 4 = not at all).

experience. **Figure 2** shows that individuals with a weak SOC report that they take longer to get over the adverse effects of the death of their spouse or partner than those with a strong SOC and illustrates work that has provided support for the idea that SOC distinguishes adaptive capacity to adverse life event experience.

General Assessment Issues

Major Life Events

Stress Appraisal

Chronic Stressors

Hassles or Daily Events

Glossary

<i>Chronic stressor</i>	An ongoing set of consistent, persistent physically or emotionally arousing demands on an organism; also referred to as a long-term difficulty.
<i>Daily event</i>	See hassle.

<i>Distal stressors</i>	Major events and stressors that occur earlier in life, usually in childhood or adolescence.
<i>Event rating, contextual</i>	An estimate of the severity of a stressor based on the objective demands posed for a particular individual who undergoes a more or less demanding stressor of that type.
<i>Event rating, normative</i>	A population-based estimate of the relative severity of a particular class of stressors.
<i>Hassle</i>	Minor life event whose effects disperse within a day or two; also referred to as a daily event.
<i>Life event</i>	A discrete occurrence believed to arouse a need for adjustment or to create negative emotions and physical reactions.
<i>Proximal stressors</i>	Recent events or stressors (e.g., within the past year).
<i>Risk factor</i>	A condition, such as stressor exposure, predisposing an individual to develop illness.

<i>Stress appraisal</i>	The individual evaluation of a stressor for its impact on well-being.
<i>Stressor exposure</i>	Exposure to life events, chronic stressors, or hassles in the environment.
<i>Threat, contextual</i>	The degree or type of demand posed by a life event or stressor.

A life events scale is a comprehensive list of external events and situations (stressors) that are hypothesized to place demands that tend to exceed the capacity of the average person to adapt. The difficulty in adaptation leads to physical and psychological changes or dysfunction, creating risk for psychological disorder or physical disease.

General Assessment Issues

It is now generally recognized that exposure to stressors in daily life, or over the course of life, is one of the most critical components of health and well-being. However, there remains ambiguity about the dimensions of stressor exposure that are involved in this process, specifically the types of stressors that have the more deleterious effects on health and that are risk factors for the development of physical and psychological illness. Variations in stressor assessment reflect different theories of how and why stressor exposure poses a risk to health.

Life events scales are the most commonly used means of naturalistic assessment of exposure to stressors, in distinction to the manipulation of stressor exposure in experimental research. Assessment of stressor exposure has been dependent on well-established research traditions in stress assessment. The first is the environmental perspective, which focuses on characteristics of events as risks for developing disease. The second is the psychological perspective, which focuses on perceptions and appraisals of threats. A third, and increasingly influential, is the life course perspective, which considers (1) the accumulation of stressors across the life span of individuals, (2) whether exposure to stressors early in life has long-term impact on health and well-being into adulthood, and (3) whether group differences in exposure to stressors (poor versus middle class; minority versus majority ethnic/racial status) are implicated in group-level differences in morbidity and mortality.

Four types of naturalistic stressor assessment predominate in the research literature: exposure to out-of-the-ordinary, demanding events, such as divorce, that have the capacity to change the patterns of life or arouse very unpleasant feelings (life events); self-reports of perceived stressfulness and appraisals of threat posed by events (stress appraisals); enduring

or recurrent difficulties and strains in an area of life (chronic stressors); and exposure to smaller, relatively minor, and normally less emotionally arousing events whose effects disperse within hours or within a day or two (daily events or hassles). Although conceived of primarily as comprehensive lists of exposure to discrete events outside the organism, life events scales often combine two or more of these approaches, sometimes including appraisals of stressors, measuring dimensions such as severity, frequency, controllability, and expectedness of events.

A frequent goal of research on stressor exposure is to establish the relationship between exposure to stressors and some health outcome in order to evaluate stress as a risk factor for disease. If the research question is to estimate the size of the association between stressor exposure and distressed mood, then the usual procedure is to use a retrospective, simple count of likely stressful life events occurring in the months prior to the measurement of mood. However, if the researcher is interested primarily in the relationship between stressor exposure and the onset, timing of onset, or recurrence of onset of a major clinical disorder, then the stressor exposure measure shifts to a determination of the type, severity, and timing of events and preexisting chronic stressors that preceded the onset of disorder. Studies of daily variation in mood or of the onset of more transient physical disorders such as colds or body aches use measures of short-term exposure to relatively minor stressors, daily events or hassles, sometimes in combination with measures of preexisting chronic stressors. Studies focusing on diseases that develop over long periods of time, such as heart disease, tend to use measures of exposure to long-term, recurrent, and persistent chronic stressors in major life roles. In practice, these methods are increasingly combined as more investigators apply the life course perspective to research on health and disease. There is considerable interest in combining the measurement of more recent (or proximal) stressors with retrospective measurement of more distal stressors, particularly severely threatening stressor exposures occurring in childhood and adolescence.

Major Life Events

Two contrasting methods of life event measurement have developed: checklist measures and personal interview measures. The latter uses qualitative probes in order to specify more precisely the characteristics of life events believed to produce the actual risk of illness and the timing of life events in relation to the outcome studies. Because of their ease of administration and the amount of exploratory health research

conducted, checklist measures predominate in studies of stressor exposure.

Checklist measures were derived from an environmental perspective on stress proposing that the basis of experienced stress is an event that brings about a demand for social, physical, or psychological readjustment. The earliest of these perspectives was the life change-readjustment paradigm, developed by Holmes and Rahe in 1967. Other theoretical perspectives on stress, such as those developed by Lazarus, Dohrenwend, and Brown, have augmented their approach in significant ways.

A typical checklist measure consists of a series of yes/no questions, asking participants to report whether any event of situation like the one described has occurred over a past period of time (from a few months to a year or more). The typical checklist measure is self-administered, although there are exceptions. Many checklist measures have been elaborated to assess more detailed information about the time of occurrence and severity. For example, some ask respondents to report the date of occurrence. Others ask for a brief written description of the situation or who else was involved in the situation. Still others ask respondents to rate the relative stressfulness of the event (from "not at all" to "very"). Self-report descriptive questions are used to estimate the severity of the event and its likely relationship to an outcome. However, the typical checklist measure does not rely on descriptive information. A typical measure sums the absolute number of event reports or sums investigator-assigned severity ratings for the events reported. The investigator-assigned ratings, termed normative, are survey-established estimates of the relative severity of stressors such as deaths, job losses, marital problems, and moves. Checklist methods yield a summary score of the estimated, normatively derived stressfulness of changes experienced over a period of time. Related to the latter point, checklist measures tend to be used in studies that use continuous symptom or mood measures as outcomes, although they are also sometimes used in exploratory studies of the onset of illness.

The ancestor of most current measures is the Holmes and Rahe social readjustment rating scale. This measure included both positive and negative events because Holmes and Rahe theorized that change per se was associated with changes in health status. Over time, checklist (and other) life events measures have moved away from the change-readjustment paradigm to an emphasis on negative or undesirable events. This trend was based on much replicated findings that undesirable events are more predictive of health problems than positive events are. Life event scales intended for use in the general

population have become more comprehensive and inclusive of events occurring to women, minorities, and other populations. Concomitantly, researchers have developed comprehensive events lists for age groups and special populations, including children, adolescents, and the elderly.

Despite their popularity, checklist measures have also been much criticized, most of these criticisms casting doubt on their reliability and validity as measures of stressor exposure. Criticisms include the vagueness and generality of the questions, which may lead respondents to misreport or overreport the occurrence of events or to report minor events as major. Life event scales have also been criticized for including events that are confounded with feeling states or psychiatric illness. There is also considerable evidence that life events scales suffer from recency bias: respondents are more likely to recall events that occur in the last month or two than those that occurred a year ago. Recall of events, moreover, is affected by mood at the time of recall.

The early development of personal interview methods for assessing life events used a theoretical perspective distinct from the change-readjustment paradigm, which informed the life events checklists. The major developer of interview methods, George W. Brown, proposed that social and environmental changes (and anticipations of those changes) that threaten the most strongly held emotional commitments are the basis for experienced severe stress. This perspective also holds that severe, rather than minor, stressors threaten health, distinguishing it from both change-readjustment and hassles paradigms.

Interview measures are not used commonly, primarily because of their greater expense and complexity. Investigators tend to use them under the following circumstances: (1) when more precise severity ratings are required; (2) where the relative timing of stress exposure and illness onset is critical to the study; (3) when the occurrence of an event, or series of events, may be related to respondent's preexisting illness or behavior (formally termed, independence from disorder); and (4) when there is interest in the specific effects of different types and severities of stressors on specific disease outcomes. Promoters of interview measures also claim that they are more comprehensive, reliable, and valid than checklist measures, although the debate is unresolved on this point. The complexity of interview methods precludes their use in lower-budget, very-large-sample (2000+), or more exploratory studies.

The Life Events and Difficulties Schedule (LEDS), developed by Brown and Harris, is the most widely used personal interview method. There are also several other personal interview methods, some based on

different rating systems (e.g., Paykel's Interview for Recent Life Events and Dohrenwend's Structured Event Probe and Narrative Rating Method). All are semistructured survey instruments assessing a wide variety of stressors, many including more distal stressors that may have occurred in childhood or adolescence. The interviews consist of a series of questions asking whether certain types of stressors have occurred over the past 12 months (or longer) and a set of guidelines or optional probes for determining more objective features of those events. The probes are used by investigators to rate the long-term contextual threat of events; contextual-threat rating is the key component of these methods because the occurrence of a severely threatening event is believed to pose a risk for the onset of illness. Contextual ratings for different types of events are documented in dictionaries and available to those who complete training in the interview methods.

Stress Appraisal

Appraisal plays an important part in life event scales, as well as theories of the stress process, most notably the transactional model of stress developed and refined by Lazarus and Folkman. The appraisal of stressors is believed to underlie the emotional experience of stress. Measures of appraisal focus on the degree to which an event threatens well-being or threatens to overwhelm a person's resources to cope.

Life event scales differ in whether they explicitly include appraisal as a component or explicitly exclude appraisal. Several measures of stressor exposure consist of assessments of how well an individual coped with stressors (although these measures are not predominant in health research). Checklist and interview measures of life events, for the most part, aim to exclude appraisal from stressor exposure assessment, although some explicitly do not. Those that exclude appraisal do so because of concerns that stress appraisal is confounded with the health and psychological outcomes that stressor exposure is supposed to predict. Indeed, researchers have speculated that some stress appraisals are caused by underlying, persistent mood disturbance or ill health, rather than vice versa. The transactional model of stress posits that appraisals can be measured separately.

Chronic Stressors

Recent research on stress and illness has turned toward emphasizing the role of persistent, continuous, or regular exposure to stressors as an important risk factor for the development of disease. There are four

main methods by which researchers measure chronic stress: (1) multi-item self-report interviews and questionnaires covering ranges of situations believed to produce chronic stressor exposure in a given setting, such as work-role demands, conflicts, and ambiguity; (2) intensive longitudinal surveys, such as daily-diary or experience-sampling methods, primarily using structured questions at regular (diary) or random (experience-sampling) intervals; (3) personal interview (contextual) measurement in life event interview instruments such as the LEDS; and (4) third-party observations of those believed to be at risk for stress exposure. The self-report interview or questionnaire is the most widely used method. Multi-item measures of chronic-stressors are an important class of life events scales.

A typical measure of chronic stressors is a set of questions designed to assess either the frequency or the severity of commonly occurring stressors in important life roles, such as work, marriage, and parenting. The strength of the multi-item approach is its grounding in the detailed, multidimensional assessment of environmental factors known to produce chronic stress, such as work and family. A weakness of the approach for some investigations is that the questions may be confounded with stress appraisal, particularly those scales assessing stressor severity.

Hassles or Daily Events

The research perspective in which measures of hassles were developed, the transactional model of stress (Lazarus), differs significantly from the research perspective in which major life event scales were developed. The hassles paradigm focuses attention on the potentially deleterious ways in which minor stressors, even those whose effects are relatively fleeting, can have negative impacts on health. Measures of hassles are life events scales, but assess exposure to minor hassles such as traffic jams, missed appointments, and quarrels with children. Although such events might in fact be major events for some people, the assumption of the hassles paradigm is that they are made more or less severe by the ways in which a person appraises and copes with the event.

Methods assessing daily events or hassles rely on diary methods of collection. These methods require participants to keep records of small events occurring over a given period of time, usually 1 day or a 24-h period, although weekly diaries have also been used. There are multiple styles of measurement: (1) open-ended approaches, which ask respondents to describe bothersome events of the day (not unlike personal interview measures, but usually self-administered

rather than conducted in person); (2) structured question approaches, which are simple yes/no response questions modeled on life events checklists; and (3) combinations of checklists with open-ended questions. Hassles scales are almost always administered in tandem with measures of stress appraisal.

Current hassles scales share the strengths and weaknesses of related approaches to the measurement of more major life events. Because diary methods of data collection rely on written and self-report, there is concern that they may confound objective event occurrence with unmeasured appraisal process. Almeida's Daily Inventory of Stressful Events uses telephone interviews and investigator ratings of narrative event descriptions to reduce some types of appraisal bias. Experience sampling methods, which involve beeping a respondent at random times during the day and asking questions about the current situation, have emerged as an alternative method for measuring daily stressor exposure.

to Experiencing Disasters?

Future Research

Glossary

Depression

A disorder of lowered mood typically associated with the loss of some or all of the following: interest, energy, pleasure, appetite, weight, concentration, and self-esteem. Disturbance of sleep, feelings of guilt, and wishing for death are also typical of depression.

Posttraumatic stress disorder (PTSD)

An anxiety disorder triggered by a traumatic and threatening event or events. Symptoms of PTSD are characteristically related to reexperiencing the event, the avoidance of triggers associated with the event, and increased arousal.

Researching the Impact of Disasters on Elderly People – Some Methodological Issues

Pan-Am flight 103 exploded in mid-air on December 21, 1988, over the small Scottish town of Lockerbie. This disaster continues to provoke media interest, not least because of the controversy over who were the perpetrators. The fireball of burning aviation fuel not only caused the death of all on board the aircraft but also death and injury to the inhabitants of the town. Survivors often had the harrowing experience of witnessing the mutilated bodies of the victims scattered over a wide area of the locality. The town hall was turned into a temporary mortuary as an army of police, firefighters, and other rescue services

descended on Lockerbie. Disasters such as Lockerbie, the Hillsborough football stadium tragedy in England, and Piper Alpha, in which an oil rig in the North Sea caught fire, provide unique opportunities to research mental disorder. The main factor in the etiology of the subsequent psychiatric problems – the traumatic stressor – is known in a disaster. This is an unusual occurrence, not only in mental health research but also in psychiatric clinical practice.

However, there are a number of special methodological problems in postdisaster research. Obviously disaster research must be retrospective, an assessment of an event that has occurred generally as a random act of nature or as the result of unforeseen human error. The presence of a large number of health-care professionals and other services brought to the site of the disaster may affect the research outcome in several ways. (In the case of Lockerbie the town's population increased from 3500 to 10,000 virtually overnight.) The health-care and support services may be effective and succeed in reducing the level of distress experienced by the disaster victims, for example through the effects of early psychological intervention programs, although these remain controversial. In addition, the psychological impact of the disaster on the rescue and recovery workers themselves is often considerable, contributes to the overall rate and level of psychological distress and psychopathology that results, and is often little acknowledged by the workers themselves until they become dysfunctional at work. This is often because of a culture in the rescue services such as the police and the armed forces that encourages a macho image and in which the acknowledgment of emotional problems is perceived by staff workers to have an adverse effect on careers. Many of the staff workers in these services are young and ill-prepared for tasks such as collecting and identifying human remains, having never previously witnessed death and dying. They are required to work at a disaster site that may be some distance from their own homes and usual family and friend support networks. The consequent media attention and the possibility of compensation for psychological damage as well as physical injury and material loss are additional factors that have to be considered in a disaster research design.

The method of assessment is important also in postdisaster studies. A desire for compensation may (in theory at least) lead to a desire on the part of

respondents to fake bad, or generate higher than warranted scores of distress. This is a phenomenon that is of even greater concern in the Internet era because of the ready access to questionnaires listing, for example, the phenomena of PTSD. In our view, therefore, such research should include not only self-report rating-scale measures but also some more objective evaluations such as clinical diagnostic assessments.

PTSD may persist for many years. A large study of Vietnam veterans found that the prevalence of PTSD was 15% after 19 years. It seems reasonable to expect that a significant number of disaster victims will continue to experience the psychiatric consequences of trauma into old age. This was certainly our impression when we were invited to examine survivors of the so-called Clydebank Blitz, the heavy German bombing of a small Scottish industrial town, important for the manufacture of ships and armaments, in March 1941 during World War II. The survivors of this event were recently encouraged to appeal to the benefits authorities in the United Kingdom for a war pension to compensate for the psychiatric consequences of exposure to two nights of intensive bombing that flattened large areas of the town and led to many casualties. Although not a systematic research study, our clinical impression was that many of these elderly people continued to experience psychiatric symptoms associated with an experience of traumatically induced stress more than 50 years prior to the clinical assessment, including full-blown PTSD.

A review has also examined the differing impact of a range of traumatic occurrences, such as the Holocaust, World War II, and the Vietnam and Korean wars. Curiously, elderly survivors of the Holocaust appeared to function well in life, unlike the combat veterans. In both groups, vivid imagery of what took place persisted, as well as disruption of sleep and a lack of trust in relationships. Furthermore avoidance of potential stressors that carried actual or symbolic relevance to the original traumatizing experience took place because these were likely to provoke a relapse or exacerbation of symptoms.

When the Lockerbie disaster occurred in 1988, there were no published studies on how traumatic stress impacted on elderly people at the time of the stress or soon after. It is possible to speculate that older people, faced with more loss-making events in a longer life, would either be better able to cope as a result or less so because of being sensitized by prior trauma. Solicitors acting for those involved in the Lockerbie explosion sought psychiatric input to assist the insurers in handling claims arising from the psychiatric damage sustained by the victims of the events

of December 1988. We decided therefore to study the clinical impact of traumatic stress on elderly people in the context of this Scottish disaster.

What Happened to the Elderly at Lockerbie

The initial assessment took place approximately 1 year after the incident, but avoided the anniversary of that event; the review took place 2 years later. Subjects were selected from a larger sample of survivors who had claimed that they had been traumatized by the explosion on the basis of a General Health Questionnaire (GHQ) score above the case cut-off level. The 31 elderly people in this category were seen, and their assessments were compared with 24 GHQ-case-designated younger survivors. Nineteen (61%) of the elderly were available for review, 2 had died, 1 was in the hospital for unrelated health problems, 1 had moved, 3 refused to participate, and 5 did not reply. Diagnosis was assigned using the *Diagnostic and statistical manual of mental disorders* (3rd edn. rev.; DSM-III-R). This classification system has since been revised, and DSM-IV is now in use. The psychological impact was measured by the Leeds scales, which assess anxiety and depression; the GHQ28, a measure of global psychological functioning; and the Revised Impact of Events scale (RIE), which quantifies posttraumatic symptoms.

The older survivors did not differ significantly from the younger in GHQ, Leeds, and RIE responses. Average GHQ28 scores were well above case level (score 4/5) 1 year after the disaster in both groups (younger 9.83 [SD, 8.20]; older 11.76 [SD 8.74]; not significant). Anxiety rather than depression tended to predominate on the GHQ and the Leeds scales. The younger and older survivors recorded high scores on the RIE intrusion (younger 15.09 [SD 9.44]; older 18.71 [SD 12.84]; not significant) and avoidance (younger 15.08 [SD 9.99]; older 17.71 [SD 11.76]; not significant) subscales. Clinically, all but five elderly survivors fulfilled DSM-III criteria for PTSD, as did all the younger subjects (Fisher test, not significant).

At the follow-up 2 years later, the proportion of GHQ cases among the elderly survivors had declined from 71 to 47%, but this was not statistically significant. The mean Leeds depression (initially 7.40 [SD 4.40]; at follow-up 3.76 [SD 2.59]; $p < 0.004$) and anxiety (initially 15.47 [SD 10.60]; at follow-up 4.87 [SD 4.87]; $p < 0.001$) ratings had declined significantly (see [Figure 1](#)). Both avoidance behavior and the level of intrusive thoughts (RIE) had also declined significantly (paired $t = 2.05$, $p = 0.07$; paired $t = 3.69$, $p = 0.003$, respectively) (see [Figure 2](#)). The proportion

Figure 1 Emotional distress in elderly Lockerbie survivors, Leeds scales and General Health Questionnaire.

Figure 2 Impact of the disaster on elderly survivors, Revised Impact of Events scale.

of PTSD cases had declined significantly from 14/19 (74%) to 3/19 (16%) ($\chi^2 10.64$, $df = 1$; not significant). Significantly, no new cases of PTSD had developed during the follow-up period. Persistent PTSD was associated with high Leeds anxiety and GHQ anxiety scores (anxiety and insomnia subscale and social dysfunction subscale). Furthermore, there was a positive correlation between persistent PTSD and a diagnosis of depression on DSM-III criteria, although none between a PTSD diagnosis and individual RIE items.

What Do We Know about the Response of Elderly People to Experiencing Disasters?

At the time we undertook our studies of elderly survivors following the Lockerbie disaster we were unaware of any other work on elderly people in such situations apart from occasional single case studies. Subsequently, reports on elderly victims of two other disasters appeared: the 1988 earthquake in Armenia and the 1995 Hanshin-Awaji earthquake in Japan.

The Armenian earthquake study was undertaken approximately 18 months after that event and involved the assessment of a total of 179 elderly and younger subjects. In young and old, as might be expected, the most traumatized were those who were closest to the earthquake epicenter. Age did not affect the level of distress suffered, regardless of the location of the victim relative to the epicenter, but elderly people tended to experience more symptoms indicative of emotional hyperarousal than did the young and to have less evidence of intrusive symptoms.

Following the Japanese Hanshin-Awaji earthquake, a study of the early psychological impact of the disaster on its victims was carried out that divided the subjects into two groups using an age cut-off of 60 years. Sixty-seven younger subjects and 75 older subjects were seen 3 weeks after the disaster. Fifty younger subjects and 73 older subjects were subsequently reviewed at 8 weeks after the disaster. The older people showed a significant decrease in symptoms in contrast with those under 60. The authors attribute this to the presence of more extensive social networks and some previous disaster experience among the older group of subjects, although it could also be argued on strong clinical grounds that previous experience of severe stress sensitizes rather than protects the sufferer from future stress related reactions.

A subsequent review looked at the effects of PTSD in groups of elderly people who were World War II veterans, were Holocaust survivors, and had experienced a natural disaster in later life. This review suggested that PTSD symptoms in the elderly can be persistent or intermittent. The severity of the trauma and premorbid psychiatric illness predisposed this group to the development of PTSD, and good psychosocial support seemed to protect against it. Older adults did not seem any more predisposed to developing PTSD than younger adults, and the symptoms appeared to be similar across the age groups.

Sadly, several other large-scale natural disasters have occurred recently – in 2004–2005 alone, the Asian tsunami, Hurricane Katrina, and the South Asian earthquake. To date, no studies of the responses of elderly people to these events have been published.

Obviously, the nature of disasters is such that they do not permit prospective study. Our sample of elderly victims was small, but remains the only long-term prospective follow-up of elderly people after a natural disaster. The multiple standardized assessment techniques used, including the application of diagnostic criteria in all cases, showed a remarkable degree of internal consistency. The major methodological flaw is that all our subjects were engaged in the process of claiming compensation from the airline on whose aircraft the explosion took place. We found that the elderly subjects had an initial emotional response to the disaster that was similar to the younger subjects, meeting the psychological case criteria in high numbers and recording high levels of anxiety and diagnosed PTSD. The level of distress diminished significantly over the 3-year time period of the studies, although one in six of the elderly subjects still had PTSD at follow-up, comparable to the findings in a study of the survivors (of all ages) of an Australian brush fire. No links between a PTSD diagnosis and specific aspects of the disaster were found at Lockerbie, although the disaster had a number of unique aspects, including a delay in recognizing that it was a terrorist act and in bringing the suspects to justice, which might be expected to adversely impact survivors' coming to terms with the event (analogous to mourning).

Future Research

Future work should attempt to assess a complete population of elderly survivors following a disaster early on and to review them over the long-term to obtain a clear idea of how traumatic stress in such situations affects older people. This work, just like the disaster-recovery effort, may require international organization, involving the creation of a disaster assessment team that can be mobilized at short notice. Such a team would be preequipped with a research design and appropriate measures. To maintain objectivity, the team needs to avoid being part of the therapeutic input or, indeed, the assessment process if a medical-legal issue is involved, such as a compensation claim. At the same time, the researchers have to strive to avoid artificially creating more stress by prolonging unnecessarily the process of assessment for an already bewildered and traumatized group of people.

Introduction

Loss Trauma Events

Responses to Loss Trauma

Childhood Loss Trauma

Adult Loss Trauma

Treatment for Loss Trauma

Resilience to Loss Trauma

Glossary

Complicated bereavement A pathological response to loss in which the usual bereavement process is impeded leading to psychopathology.

Eye movement desensitization and reprocessing (EMDR) Loss

A treatment for trauma responses involving desensitization and rapid eye movements.

Loss trauma

Death or long-term separation from a close other, but also experiences with loss of self-identity, security, or trust in others.

Posttraumatic stress disorder (PTSD) Traumatic event

A type of event combined with a pathological response, which involves characteristics of both trauma and loss.

A classified anxiety disorder, with distinctive symptoms, specifically in response to a traumatic event.

A type of severe life event, often involving horror, which has fundamental implications for one's safety and place in the world. Can be single or multiple.

Traumatic grief

A pathological response to death of a close other with symptoms similar to PTSD.

Introduction

The investigation of loss trauma is a relatively new psychological subdiscipline, based on the specification of a particular type of traumatic event (that of the death of a close person), with the identification of specific pathological responses, which, although similar to those identified in relation to other traumatic events, have identifiable symptoms associated with a grief response. Its identification as a new focus of study is marked by a new journal (*Journal of Loss and Trauma*) and by organizations such as the National Institute for Trauma and Loss in Children. It is also marked by variants of treatment protocols, which attend specifically to elements of the loss in trauma. However, there is as yet no widely recognized classification of traumatic grief as a disorder. The word trauma has a dual meaning, referring both to an event or circumstance and to the psychological impact of that event on an individual's well-being. In this article these meanings will be differentiated by traumatic event and trauma response.

Loss Trauma Events

A traumatic event is a type of life event, that is, an external circumstance that happens at a defined time. However, as trauma, it constitutes an event with a particularly high level of threat and unpleasantness, which has implications for a person's sense of safety and place in the world. Thus, it is usually sudden and unpredicted and is often accompanied by circumstances that involve horror or intense shock. Trauma events are usually public (e.g., witnessing a suicide, being involved in a terrorist bomb attack, being in the line of a major flood or tsunami) and are common in combat and war situations with both soldiers and civilians. However, trauma can also be private, for example, physical or sexual assault, which involves threat to life or personal integrity. Trauma events can be single or multiple, with different pathological responses associated with them. Loss trauma events are often single when deaths of others are involved. However, a context of severe illness, caring responsibility, or enforced separation may constitute a multiple or chronic course to the traumatic experience.

Loss trauma identifies traumatic circumstances specifically with loss events, usually the death of a close person. This usually involves a parent, partner, child, or close relative or friend, and usually under unexpected or horrific circumstances. Thus, suicides, accidents involving physical mutilation, or circum-

stances with a random aspect such as freak accidents would all be encompassed in loss trauma events. Loss trauma can also include losses of children or babies, for example, birth of a stillborn child or a child with multiple handicaps or deformities. As a category of event, loss events not only can involve deaths of close others and separations from a close other (e.g., parent, partner, child), but also can involve psychological losses such as loss of security (e.g., loss of job or home), sense of self (e.g., loss of reputation or physical losses such as limbs), or a meaningful relationship (e.g., revelation or betrayal). However, there has been less investigation of these wider losses in terms of loss trauma.

Responses to Loss Trauma

Any traumatic and major loss event will have some immediate psychological consequences such as shock, distress, denial, or numbing and possibly flashbacks to the event. However, in a small proportion of cases, posttraumatic stress disorder (PTSD) will ensue, a classified psychological anxiety disorder. Complicated bereavement responses may set in whereby the bereavement process is incomplete, the loss is unresolved, and traumatic grief may occur. Traumatic grief is seen as a variant of other disorders such as depression and PTSD and does not have a distinct classification in standard psychiatric manuals. However, there is ongoing debate about whether traumatic grief should constitute a disorder in its own right.

Posttraumatic Stress Disorder (PTSD)

PTSD involves response to a traumatic event described as actual or threatened death or serious injury, or a threat to the physical integrity of self or others. PTSD is one of several anxiety disorders. It was originally used for explaining combat reactions in terms of shell shock but is now linked with a range of traumatic events. PTSD symptoms exist for at least 1 month and include preoccupation with the horror of incident, hypervigilant scanning of the environment for potential threat or danger, avoidance of situations, futility about the future, shattered world view, excessive anger, cognitive dysfunction, and prolonged impaired social or occupational functioning. PTSD is often typed by whether the trauma provoking it is acute or chronic, that is, single exposure or multiple incidents and exposure. The latter is considered the most damaging in terms of functioning, particularly when occurring in childhood. In terms of prevalence, while it is estimated that most people (90%) experience at least one traumatic event in a lifetime, only 10% develop a history of PTSD. This is more likely

after certain events. For example, prevalence ranges from as high as 50% in response to rape to less than 1% after hearing of serious injury to close relative or friend.

Complicated or Pathological Bereavement

When the response to loss (usually the death of a close person) does not follow the usual progression through the stages of grief work leading to acceptance, it is considered a pathological bereavement response. It impedes the development of new ties and inhibits adaptation to the loss both personally and socially. When this occurs in childhood, it is argued, it impedes adult functioning and leads to long-term problems. However, not all researchers accept the inevitability of grief work and claim that adaptive responses can occur without evidence of following particular stages in the process. Grief work thus may be required only following more severe losses or for individuals with high levels of distress or vulnerability to loss.

Traumatic Grief

Traumatic grief is a relatively new term that combines trauma with bereavement or grief responses. It is provoked by the death of a significant other and includes symptoms similar to PTSD but specifically focused on the lost person, including intrusive, distressing preoccupation with the deceased, hypervigilant scanning of the environment for cues of the deceased, the wish to be reunited with the deceased, separation anxiety features, futility about the future, difficulty acknowledging the death, shattered world view, and anger together with impaired social functioning.

Studies have examined traumatic loss among groups such as elderly caregivers of terminally ill spouses, young adults who lost a friend to suicide, and parents who lost a child in a traffic accident. These have shown ensuing symptoms in two categories: (1) separation distress, involving preoccupation with thoughts of the deceased, longing, searching, loneliness, and impaired functioning, and (2) traumatic distress, feeling disbelief, anger, mistrust, and detachment from others.

Peritraumatic Dissociation

Peritraumatic dissociation is a dissociated response to loss with expression of psychological shock, as indicated by a sense of reality having been abruptly altered. Thus, being in a daze, feeling disoriented, numb, or on automatic pilot, and experiencing the surroundings as unreal are typical, together with star-

ing into space or feeling like a spectator. This response is usually associated with traumatic grief. The greater the experience of shock and overwhelming emotion, the more likely the dissociation, with PTSD following afterward. This is similar to the symptoms described in complicated bereavement or traumatic grief.

Childhood Loss Trauma

Loss trauma including loss of parents, loss of partners, and loss of close friends may be expected to occur at any life stage. However, when such losses occur off-time (i.e., nonnormatively), this may be a contribution to their traumatic nature and impact. Thus, losses of parents in childhood, losses of children, and widowhood in early- or mid-adulthood are all candidates for traumatic loss.

Psychoanalytic approaches to depression emphasize its relationship to loss experience, particularly in childhood. As a result there has been much investigation of childhood loss of a parent and vulnerability to adult disorders such as depression. Detailed investigation of childhood deaths of parents has shown that these have marked long-term impact only when neglectful or abusive parenting follows, or when the loss is considered aberrant in terms of abandonment. When death of a parent in childhood occurs in otherwise caring and supported circumstances, no long-term dysfunction occurs.

Childhood trauma has been extensively studied by Leonie Terr, who identified different symptoms following from single-blow or multiple-blow trauma. Type I trauma, that following a sudden single shock, was found to evince symptoms such as full repeated memories, strangely visualized or repeated, repetitive behaviors, trauma-specific fears, omens, and misperceptions. In contrast, type II trauma, following multiple or chronic shock, evinced denial and numbing, dissociation, and rage. In both instances childhood trauma led to changed attitudes about people, aspects of life, and the future.

Adult Loss Trauma

The most typical adult losses concern loss of a child or pregnancy and loss of a partner. These events can occur at any age, but death of a partner is clearly more common (and more normative) in later life. Again, the traumatic nature of the losses include suddenness and horror. PTSD is observed after pregnancy loss, and given that most losses of pregnancy are sudden and unexpected, these can constitute trauma, although those pregnancies that are lost in later weeks (or taken to term and ending in stillbirth) or those in which the fetal loss involves pain and bloodshed are

more likely to constitute loss trauma. However, even with miscarriage in earlier weeks, a small proportion (7%) develops PTSD symptoms. However, more common responses are depression (30–50%) or anxiety (32%) occurring within 6 months of miscarriage. Research into widowhood (e.g., by Colin Murray-Parkes in the 1970s) showed individual variation in responses, but showed complicated bereavement with aspects such as intrusive thoughts, avoidant behaviors, yearning, loneliness, and loss of interest. Further work with elderly widows following an extensive caring role showed distinct traumatic grief responses.

Treatment for Loss Trauma

The core of treatment for trauma involves being able to talk about the traumatic experience within a therapeutic trusting relationship. The dilemma for the therapist is that reminders of trauma can trigger symptoms of PTSD, so symptoms can in the short term be worsened. Thus, trauma treatment must balance the degree of processing (of negative information) with containment (by the therapeutic relationship) in a secure setting. There are various approaches to treating trauma, which are not necessarily specific to loss trauma.

Critical Incident Stress Debriefing

Debriefing was originally developed for limited use as a brief group intervention to help mitigate psychological distress among emergency response personnel. This was then developed to be used on an individual rather than a group basis. However, global application of debriefing has been shown to be relatively ineffective and may at times impede recovery. This may be because it has been removed from its original purpose as a group bonding exercise for emergency workers, but also because it may impede the natural support that individuals can receive from those close at times of emergency. It has been argued that formalized debriefing can pathologize normal reactions and thus neutralize normal coping responses.

Cognitive-Behavioral Treatment (CBT)

CBT treatments used for affective disorder can help individuals to understand and manage anxiety associated with the trauma-related stimuli. Exposure

treatment involving repeated confrontations with memories of the traumatic stressor in therapeutic settings has shown successful outcomes, although not specifically adapted for trauma responses. CBT can be helpful in conjunction with other techniques such as eye movement desensitization and reprocessing.

Eye Movement Desensitization and Reprocessing (EMDR)

EMDR was discovered by Francine Shapiro; it is a desensitization process that involves bringing the traumatic memory to mind while the patient simultaneously moves the eyes from side to side, following the movement of the therapist's finger back and forth in front of the face. After a series of eye movements the patient is instructed to let go of the traumatic images and say what comes to mind. Over the course of successful treatment, the emotional distress abates, traumatic images become less intrusive, and beliefs about the self become more positive. There is general agreement that the technique is successful in conjunction with other therapeutic techniques, but the precise mechanism for its action is not well understood, although it may directly work on brain mechanisms.

Dialectic Behavior Therapy (DBT)

DBT was invented by Marcia Linehan and although originally used mainly for borderline personality disorder in which self-harm is involved, it was found to also be effective for trauma. The therapy requires learning skills for coping with painful emotional states that lead to self-destructive behavior. Behavioral skills and emotional control are enhanced through emphasis on actively teaching and reinforcing adaptive behavior. It can be conducted both on an individual psychotherapy basis and in group meetings. Again, it is not specifically designed for loss trauma but has elements required to deal with some traumatic grief responses.

Resilience to Loss Trauma

Experience of traumatic events is common, but experience of trauma psychopathology is fairly rare. Therefore, it is argued, resilience must exist in the face of encountering trauma or, conversely, some

individuals are vulnerable or sensitized to loss trauma. As with other psychological disorders, factors influencing vulnerability to PTSD include lack of social support, lack of education, family background, prior psychiatric history, and aspects of trauma response such as dissociative states.

It has been argued that resilience to loss trauma has been underestimated because of research focus on individuals developing disorders, which biases the field toward vulnerable individuals. For example, absence of grief, usually pathologized among patients, may in fact indicate resilience in hardier individuals. It is argued that there is little empirical support for the notion of delayed grief and that some individuals may adapt quickly to loss without going through grieving stages. Similarly, PTSD-type symptoms are common in the first few weeks after a traumatic event, but in most people these disappear and the full syndrome does not occur, thus indicating some process of resilience. Resilient and recovering individuals are often put into same category, since chronicity of symptoms is a key marker for pathological reactions and more resilient individuals adapt more quickly and may be perceived to have been treated rather than have drawn on personal resilience factors.

Glossary

*B cell-
dependent
area*

Primary and secondary follicles located in the superficial cortex, underneath the subcapsular sinus. B cells migrate to and are organized into follicles.

Cortex

A major area of the lymph node consisting of a superficial cortex and a deeper region, the paracortex.

*Fibroblast
reticular cell*

Network composed of collagen-containing reticular fibers that are produced by

<i>(FRC)</i> <i>network</i>	FRCs. It forms the infrastructure of the lymph node.
<i>Lymph node</i> <i>(LN)</i>	A key organ of the peripheral immune system.
<i>Medulla</i>	The second major area of the lymph node located beneath the paracortex, closest to the hilum, and subdivided into medullary cords and medullary sinus, which drains into the efferent lymphatic vessel.
<i>Paracortical cords</i>	The paracortex is made up of multiple cords. Each is a functional repeating unit of the cortex, which stretches from a medullary cord to the base of a B cell follicle. It consists of the central high endothelial venule (HEV) surrounded by a perivenular channel, a corridor, and a cortical sinus. HEVs are specialized segments of vessels localized deep in the paracortex, whose luminal surface is lined by high cuboidal endothelial cells serving as transmigration points for lymphocytes emigrating from the bloodstream to the lymph node. Perivenular channels are narrow spaces along the HEVs into which lymphocytes arrive, having crossed the endothelium, and where they seem to accumulate. To reach the corridor, they must next cross the barrier of overlapping fibroblast reticular cells, which form the perivenular sleeve. In the corridor, lymphocytes are able to migrate more freely and interact with antigen-presenting cells lining the corridor walls. The cortical sinus is a fluid-filled compartment that bounds the outer surface of the paracortical cords and connects the subcapsular sinus with the medullary sinuses.
<i>T cell-dependent area</i>	The interfollicular regions and the paracortex of the lymph node. T cells migrate preferentially to these anatomical locations.

Lymph nodes (LNs) are fundamental functional units of the immune system. They are the organs in which immune cells transact their business. Distributed strategically throughout the body, they are localized close to major junctions of the lymphatic channels. Naive lymphocytes recirculate continuously through the peripheral lymphoid organs, including LNs, passing from blood to lymph and then back to blood via the thoracic duct. LNs play a key role in collecting information necessary for entering lymphocytes to make a decision about whether to respond to an antigen or to become tolerant and/or die, thus avoiding autoimmunity. Lymph draining the extracellular spaces of the body carries antigens from tissue sites to the nearest LN, where afferent lymphatic vessels converge. Antigens thus delivered to the LN are trapped, screened, and presented to those rare immune cells in the pool of T and B lymphocytes migrating through the node that are capable of antigen recognition. The process of recognition involves Ig receptor (e.g., 1 in 100 000 cells) on B cells and T cell receptor (TCR) on T lymphocytes and initiates a series of events orchestrated within the milieu of the LN, culminating in generation of an antigen-specific immune response. Virtually all primary immune responses take place in LNs and other secondary lymphoid organs, such as spleen or gut-associated lymphoid tissue. Hence, LNs are extraordinarily important sites of interactions between immune cells and antigens and are especially adapted to facilitate these interactions.

Architecture of Lymph Nodes

LNs are small, oval structures (about 0.5 cm or less in diameter) with complex architecture, which differs

Figure 1 A schematic view of a lymph node in cross-section, showing its various components.

Figure 2 Functional units of a lymph node. (a) Paracortical cords in a longitudinal view. A white box indicates a representative cord. Note an extensive network of reticular fibers surrounding each postcapillary venule and high endothelial venules (HEV) shown as darker regions of the venules. Paracortical cords begin at the base of follicles (F), run the length of the cortex, and coalesce into medullary cords at the corticomedullary junction. Spaces around paracortical cords are cortical sinuses (CS). SCS, subcapsular sinus at the margin of the LN. Reproduced with permission from Kelly (1975). (b) A cross-section of a paracortical cord, indicating a control HEV surrounded by perivascular channels (PVC) and corridors supported by a framework of fibroblastic reticular cells (FRC) and bounded by sinus-lining cells (SLC).

between species. The basic structural elements of lymph nodes are the cortex and the medulla (Figure 1). A section through a LN shows the outermost capsule; the subcapsular sinus draining afferent lymphatic vessels; the cortex, consisting of an outer region made up of B lymphocytes organized into lymphoid follicles and of deeper paracortical cords made up mainly of T lymphocytes; the medulla, organized into medullary cords, consisting of strings of macrophages and

antibody-secreting plasma cells; and medullary sinus connected with efferent lymphatic vessels. This basic architecture of LNs undergoes dramatic changes during an antigenic challenge or in response to neural or inflammatory stimuli, and it is this remarkable plasticity of the critical architectural elements of a lymph node that facilitates immune cell interactions.

The cortex of a lymph node in larger animals and humans is subdivided into 10 or more lobules separated by fibrous bands called trabeculae (Figure 1). Each lobule has the follicle with a germinal center, the B lymphocyte-dependent area, and the paracortex corresponding to the T cell-dependent area. This area accommodates paracortical cords, which form the fundamental structural unit of the lymph node paracortex. Figure 2a provides a lateral view of paracortical cords, each with a central postcapillary high endothelial venule (HEV) bordered by the cortical sinus. Paracortical cords begin at the base of follicles and run parallel to each other to the corticomedullary junction, where they coalesce into medullary cords. In cross-section, a paracortical cord is a cylinder composed of sinus-lining cells at its periphery, concentric rings of barrier-type cells called fibroblastic reticular cells (FRCs), and a central HEV (Figure 2b). The concentric arrangement of FRCs creates a perivenular channel. The spaces between the rings are filled with lymphocytes and other cells and FRCs from an outermost layer of the channel, enclosing it like a sleeve. Outside of the sleeve is a fluid-filled corridor bounded and supported by a network of FRCs. The corridors are 10–25 μm in diameter, and they join with and split from each other, creating no barriers and allowing for efficient cell migration. The boundary of flat sinus-lining cells separates the corridors from the surrounding paracortical sinus. A representative radius of a cord is 50–100 μm or roughly 10 lymphocyte diameters. However, paracortical cords are pliable structures, capable of stretching to easily accommodate masses of migrating lymphocytes.

The outermost aspect of a lobule, situated underneath the subcapsular sinus, is the B-dependent area of a LN. It is composed of tightly packed B lymphocyte formations referred to as primary follicles. Germinal centers are formed within follicles on antigenic stimulation of B cells and represent areas of extensive B cell proliferation. Occasional T cells are also present. An important cell resides in the follicular area, the so-called follicular dendritic cell (FDC), which is responsible for trapping and presenting antigens to B cells. The FDC is a highly specialized type of DC that binds immune complexes via Fc and complement receptors, internalizes them, and holds them for long periods of time. This function of FDC is crucial for memory B cell development. The germinal centers are

Figure 3 A diagram illustrating continuous trafficking of lymphocytes through a LN. (a) Antigen enters the nodes through afferent lymphatics, and small naive lymphocytes enter via the blood vessels from the bloodstream. In the cortex, lymphocytes enter through HEV (not shown). (b) Once in the node, T cells migrate to T cell-dependent areas, whereas B cells migrate to follicles. Antigen is taken up and processed by dendritic cells (not shown). (c) Lymphocytes that recognize the antigen stop recirculating, enlarge or blast and begin to proliferate. Masses of blasting T cell are seen filling the paracortex. Lymphocytes that do not recognize antigen continue migrating and leave the LN via the efferent lymphatic vessel. (d) After about a week, plasma cells appear in the medulla, and effector lymphocytes and antibodies leave the LN via the efferent lymphatic vessel.

surrounded by dense formations of small memory B cells. Interfollicular areas are populated by T cells and represent T-dependent regions of the LN. Follicles provide the microenvironment for the exposure of B cells to trapped antigens and for their proliferation. They are the anatomic site for somatic mutations. Although B cell differentiation to plasma cells occurs mostly in the deep paracortex and medullary cords, follicles are the site of B cell affinity maturation and memory development.

The medulla of a LN is a loose network of medullary cords and sinuses situated in the hilar area and separated loosely from the paracortex by a network of connective tissue fibers. Medullary cords contain both T and B cells and most of the plasma cells in the LN. B cells complete their maturation into antibody-producing plasma cells in the medulla, and lymph exiting via the efferent lymphatics is enriched in antibodies. In addition, scavenger macrophages line

the medullary sinuses and are responsible for the removal of particulate antigens found in the lymph.

Lymph vessels carrying interstitial fluid deliver antigens to the LN. The lymph enters from afferent lymph vessels into the subcapsular sinus and is channeled around and through trabecular sinuses, across the LN parenchyma toward a medullary network of sinuses. From there, it can leave the LN via efferent lymph vessels and travel to the next LN in the chain. The intranodal lymph channels are enclosed by FDCs, sinus-lining endothelial cells, and macrophages, which sample the lymph and transport antigenic material for presentation to B and T cells. Antigens in the lymph do not have free access to the lymphocyte compartment, and FDCs serve to select and transport lymph-borne molecules to be presented to T and B cells that home to LNs from the blood.

Overall, the architecture of a LN is characterized by a high degree of compartmentalization, which appears to be necessary in order to maintain the

constant and directed flow of lymphocytes from one compartment to another and to allow for cellular interactions to occur at the time and place best suited for optimal immune responses.

Lymphocyte Migration within the Lymph Node

Figure 3 is a diagrammatic representative of trafficking of lymphocytes in, within, and out of the LN. Lymphocyte migration is a continuous process. Naive lymphocytes enter the node from the bloodstream via specialized structures called HEVs in the paracortical cords. Adhesion molecules on the surface of lymphocytes are instrumental in their binding to and the subsequent transmigration through the high cuboidal endothelium. Antigens enter the LN through the afferent lymphatics and are trapped by specialized cells (dendritic cells [DCs]) for presentation to lymphocytes. Only the rare lymphocytes recognizing the antigen via the TCR or BCR are activated and stop recirculating. Lymphocytes that do not recognize antigen continue migrating through the LN and leave it via the efferent lymphatic vessel (**Figure 3c**).

Lymphocytes entering the paracortex cords from blood via HEV move outward through perivenular channels made up of concentric rings of FRCs. Lymphocytes spend 10–100 min moving through these channels, which are rich in extracellular matrix (ECM) components and provide an excellent substrate for lymphocyte migration. To reach the cord, lymphocytes must once again transmigrate, this time through tightly overlapping FRCs enclosing the perivascular channels like a sleeve. Once within the next compartment, called the corridor, the route of lymphocytes depends on whether they are T or B cells. T cells migrate to the T-dependent areas, whereas B cells migrate to the follicles. It is not known how the cells select their route or how their traffic is directed. Lymphocytes end their journey through the cord by migrating between the sinus-lining cells into the cortical sinus.

The migration of lymphocytes through the cortex proceeds radially outward, from the HEV lumen to the outer sinuses. It is remarkable that during this journey lymphocytes manage to traverse across three cellular boundaries: the HEV endothelium, the FRC boundary in perivenular channels, and the sinus-lining cell. In addition, lymphocytes migrate more or less up and down within the cortex. They do so by crawling along the corridor wall or sinus boundaries, both richly expressing the ECM components. This oriented migration within the cortex is crucial for lymphocyte interactions with antigen-presenting cells (APCs) and for the connection between the follicular

areas and the medulla. Also, the ability of differentiated effector T cells or plasma cells to leave the LNs via efferent lymphatics depends on the open routes of migration within the cord.

Antigen-Driven Interactions in the Lymph Node

The presence of an antigen dramatically alters the appearance and size of the LN. Upon entering the node environment through afferent lymphatics, antigens are taken up by sessile APCs referred to as interdigitating dendritic cells (IDCs) and found in the cortex. These cells migrate via lymph from tissues to the corridor, where they attach to FRCs, providing an optimal milieu for lymphocyte–APC interactions. Aside from enlarging the surface available for these interactions, IDCs are rich in costimulatory molecules and cytokines. Lymphocytes typically spend 3–6 h in the corridor space. Thus, migrating T lymphocytes have the opportunity to screen IDCs immobilized on the corridor walls for antigens (peptides) presented by the major histocompatibility complex (MHC). When the TCR on the T cell encounters the peptide it recognizes, activation of the T cell occurs. This process can occur anywhere in the corridor space, allowing migrating T cells an opportunity for screening multiple IDCs along the way. Thus, corridors of the paracortex are the ideal sites for interactions of IDCs, T cells, and B cells, where the generation of the immune response is facilitated by efficient cell-to-cell contact. They also provide a suitable environment for the proliferation of activated T cells.

When a T cell traversing the paracortex meets its cognate antigen, the TCR transmits activation signals to the nucleus, and T cell proliferation begins within the corridor. Simultaneously, B cells migrating through the paracortex or moving along the axis of the corridor are also likely to encounter antigen recognized by the Ig receptor and to initiate proliferation. In an environment rich in cytokines secreted by activated T cells, B cells undergo differentiation. The clonal expansion of antigen-specific T and B cells leads to their accumulation in the corridors and to marked distention of the cords. The size of a LN increases dramatically during an immune response. In addition to ballooning, paracortical cords undergo elongation in reactive LNs, and endothelial cells in HEV also proliferate. Thus, the entire size of the LN increases several-fold in a relatively short period of time. Conversely, when the depletion of lymphocytes occurs, e.g., during thoracic drainage, the diameter of the cord shrinks. Large differences in the size of the cortex due to changes in lymphocyte numbers are the basis for a common perception that reactive LNs are large and

nonreactive LNs are small. The enormous plasticity of LNs depends on their infrastructure of collagen fibers and FRCs, forming a loose reticular network amenable to shrinking and extension. The LN also has a network of nerve endings that connects it to the central nervous system (CNS). In an enlarged reactive LN, changes in the migration rate of lymphocytes occur: the traffic along the long axis of the cords becomes prominent, with effector T cells and differentiating B cells moving toward the medulla and other B cells, those destined to become memory cells, moving toward the follicles. This is possible because extended cords allow for easy access and enhanced lymph flow to the interfollicular area at the base of follicles. Similarly, medullary cords and sinus are also extended in reactive LNs and are able to accommodate more lymphocytes now migrating toward the efferent lymphatic vessel in the hilum. Before lymphocytes exit the LN, they spend a period of time in the medulla. Here, in the environment rich in cytokines and in the presence of helper T cells, B cell maturation into antibody-secreting plasma cells takes place. Antigen-specific effector T cells and plasma cells leave the LN through the efferent lymphatic vessel to enter the bloodstream and eventually to reach the site of infection or repopulate sites of antibody production, respectively.

Significance of Lymph Nodes

Because lymph-borne antigens enter the LN continuously and immune responses are generated to a variety of antigens at all times, immune cells leaving the LN contain effector cells primed to deal with a variety of different antigens. The LN environment is structured and organized to facilitate entry and migration of naive lymphocytes to areas of antigen presentation, to promote antigen recognition, to allow for activation and proliferation of antigen-specific T and B cells, and, finally, to assure the availability of immune effector cells to sites of infection. This series of events is accomplished in 4 to 6 days in primary immune responses and in a much shorter period of time in a secondary response. The presence in the follicular compartment of memory B cells surrounded by interfollicular T cells assures that anamnestic responses are initiated promptly at the site of antigen entry. Migration of activated T and B cells from the follicular area along the length of extended paracortical cords to medulla proceeds rapidly during secondary immune responses and may be facilitated by chemokines, by cytokines produced by activated lymphocytes or accessory cells, and perhaps by the directional flow of fluids in the corridors. The regulation of directed migration of lymphocytes during primary or secondary immune responses is a subject

Figure 4 A schematic representation of stress-induced, glucocorticoid-mediated effects on lymphocyte entry into LN and on cytokine production by lymphocytes present in LN. ACTH, adrenocorticotropic hormone; MIF, migration inhibitory factor, LPS, lipopolysaccharide.

of intense investigation. To home to the LN, lymphocytes must execute a series of adhesion and signaling events that involve a variety of molecules. First, tethering and rolling of lymphocytes entering HEV of LNs is mediated by L-selectin (CD62L) and its ligands, such as MECA-79. Next, arrest of rolling lymphocytes is mediated by the integrin leukocyte function-associated antigen 1 (LFA1), interacting with ICAM1 and ICAM2 expressed on HEV. Activation of integrins on lymphocytes is mediated by the CC chemokine ligand 21 (CCL21, SLC, 6CKine) constitutively expressed by HEV cells. It binds to its receptor (CCR7) on lymphocytes. A second CCR7 ligand, CCL19 (ELC, MIP3 β) is expressed by the lymphatic endothelial and interstitial cell but not by HEV. Other integrin-activating signals involving chemokines and their receptors exist, and it is thought that T cells and B cells respond to different signals in HEV. Activation-dependent adhesion steps allow lymphocytes to stick firmly to HEV and to emigrate through the vessel wall and enter the LN environment. The LN represents a series of distinct micro environments, each adapted to optimize the function of immune cells. The key element is migration of these cells from one compartment to another. It is important to note that the migration of lymphocytes within the node can proceed in either of two directions, from HEV outward to the sinus in the paracortical cord or from the follicular area to the medullary sinus at the hilum. Naive lymphocytes entering the node via HEV take the first route; once activated and/or proliferating, lymphocytes tend to take the second path. The regulated movement of fluids and cells within the LN compartments is a wonderful example of the efficiency of the immune system in

executing primary and secondary antigen-specific responses.

Interactions between the Central Nervous System and Lymph Nodes

Recent advances in the field of neuroimmunology have shown that the CNS and the immune system are intimately linked. The CNS influences responses of the immune system through the release of humoral factors such as cortisol or epinephrine from the hypothalamic-pituitary-adrenocortical (HPA) axis. Glucocorticoids released as part of a systemic stress response influence (downregulate) immune responses profoundly. Communication between nervous and immune systems is also maintained by the efferent neuronal sympathetic nervous system in lymphoid organs. LNs are innervated so that a close association exists between autonomic nerve terminals and immune cells. Local synthesis and colocalization of norepinephrine, neuropeptides, such as neuropeptide Y, and opioids have been documented in the nerve terminals of nerve fibers located in LNs. Immune cells present in this microenvironment have specific surface receptors for neurotransmitters and neuropeptides and are responsive to signals transmitted via the receptors. In addition to efferent nerve terminals, LNs contain afferent nerve fibers characterized by the expression of receptors for cytokines or other factors produced by immune cells. Thus, bidirectional traffic of biochemical mediators between the CNS and immune cells regulates their interactions.

An example of chemically mediated signal transmission in response to stress is shown in [Figure 4](#). In this schema, stress or infectious agents induce the release of glucocorticoids from the HPA axis. Glucocorticoids have potent anti-inflammatory and immunosuppressive effects, including the downregulation of lymphocyte functions and of their migration into the LN. In the presence of cortisol, immune cells begin to produce a cytokine, migration inhibitory factor (MIF), which counteracts inhibitory effects of glucocorticoids at the local level. The pituitary also produces and releases MIF into the systemic circulation. MIF suppresses glucocorticoid production and restores the immune balance.

Trafficking of lymphocytes is fundamental to the generation of immune responses. Glucocorticoids inhibit lymphocyte migration into LNs and disrupt lymphocyte recirculation.

Lymphopenia observed in the presence of steroids is not due to death of lymphocytes but to redistribution of the circulating lymphocyte pool. Lymphocytes that normally enter LNs now migrate away from

them, with the net result being the downregulation of lymphocyte entry into the LNs. The molecular mechanism responsible for this effect is a glucocorticoid-induced decrease in expression of L-selectin (CD62L), also known as a lymph node homing receptor, and of CD44 Hermes protein on the surface of lymphocytes. Because these adhesion molecules are involved in lymphocyte-HEV interactions and are necessary for lymphocyte entry into LNs, dysregulation of their expression naturally interferes with homing. It is probable that these interactions are not direct but are mediated via cytokines, whose local production is inhibited by glucocorticoids (see [Figure 4](#)). The profound effects of stress on the immune system are partly mediated via neurotransmission in LNs. Thus, the understanding of LN architecture and of lymphocyte migration patterns in LNs is necessary for the appreciation of stress-induced alterations in immune responses. The various aspects of the CNS-immune system communication and, especially, the role of cytokines in orchestrating these interactions are being intensely investigated today.

Introduction

Origin and Development

B Lymphocytes

T Lymphocytes

Natural Killer (NK) Cells

Glossary

Anamnestic response An accelerated secondary immune response.

B cell Large, metabolically active B cells.

lymphoblasts

Class I major histocompatibility complex (MHC)

The MHC expressed on all nucleated cells.

Class II major histocompatibility complex (MHC)

The MHC expressed mainly on antigen-presenting cells.

Cytokines

A diverse group of multifunctional proteins that play a key role in a variety of biological processes, including cell growth and activation, inflammation, immunity, hematopoiesis, tumorigenesis, tissue repair, fibrosis, and morphogenesis. Chemokines are a subgroup involved in chemotaxis. Cytokines are synthesized in a variety of cell types, including lymphocytes and cells of the mononuclear phagocyte system.

Endocytosis

Ingestion of molecules by the cell.

Epitope

Antigenic determinant.

Erythropoietin

The growth factor required for the generation of erythrocytes from the pluripotential stem cell.

Granulocyte/monocyte-colony stimulating factor (GM-CSF)

The growth factor required for the generation of granulocytes and monocytes from the pluripotential cell.

Immuno-globulin
Stem cell

The antibody containing fraction of serum.

A self-renewing undifferentiated cell capable of developing into specialized cells.

Introduction

In vertebrates, the specialized function of acquired or adaptive immunity is assigned to the immune system. Like other specialized organs, the immune system comprises a number of differentiated cells that contribute to its special function; unlike most other organs, however, the immune system is distributed throughout the body (see **Immune Response**). This decentralized anatomical structure best serves its purpose of providing immunological surveillance and protection. The distinguishing features of the acquired immune response are its specificity (the ability to distinguish one antigenic molecule from another) and its memory. The immune system must recognize and respond to the vast universe of antigenic determinants and must learn to respond more vigorously at a second encounter. The cells specialized to serve these critical functions are the lymphocytes. This article focuses on the major population of lymphocytes: B lymphocytes, T lymphocytes, and natural killer (NK) cells.

Origin and Development

Figure 1 diagrams the early development of the hematopoietic system, of which the immune apparatus is a component. All of the blood cells develop from a single multipotential or pluripotential stem cell. Phylogenetically this cell arises in the yolk sac. In mammals, the pluripotential stem cell transfers to the liver during embryonic development, but later, during gestation and birth, it migrates to the bone marrow. Like all stem cells, it is capable of self-renewal but can differentiate into a number of specialized progenitor or precursor cells. These include the erythrocyte progenitor, which eventually develops into the erythrocytes; the megakaryocyte progenitor, which is the eventual source of platelets; and the myeloid progenitor of the granulocytes and monocytes, which is the source of all of the granulocytic leukocytes, such as polymorphonuclear neutrophils, eosinophils, and basophils and of the monocytes of the blood and the macrophages and dendritic cells of the tissues. Finally, the lymphocyte progenitor is the source of B lymphocytes, T lymphocytes, and NK cells. The production of these progenitor cells, as well as their continued differentiation into the mature functional cells of the lymphopoietic system, is driven by a family of peptide messengers, referred to collectively as colony-stimulating factors. At least two of them, erythropoietin, which promotes the production of erythrocytes, and granulocyte/monocyte-colony stimulating factor (GM-CSF), which fosters production

Figure 1 Development of the lympho-hematopoietic system.

of the granulocyte/monocyte lineage, have been isolated and used clinically to treat deficiencies of the respective cell populations.

B Lymphocytes

As indicated previously, B lymphocytes arise from the pluripotential stem cell in the fetal liver and later in the bone marrow. Directed by several stimulating factors, it matures into a functional B lymphocyte. These cells comprise approximately half of the approximately 10^{12} lymphocytes in the human body. They represent about 20% of the circulating lymphocytes but a majority of those found in the organized lymphoid tissues, such as the spleen and lymph nodes. The critical event in B cell maturation is the production of an antigen-specific receptor and its expression on the cell surface.

The B cell receptor (BCR) is a membrane-bound form of the immunoglobulin (Ig) molecule. The clonal selection theory of the immune response requires that there be an enormous diversity of these cell surface receptors, enough to bind any antigenic determinant or epitope that the B cell may encounter. The BCR is a heterodimeric molecule consisting of two heavy and two light chains, both of which have variable regions that contribute to the epitope-specific binding site. The required diversity of the receptors is produced by a specialized process of recombination, wherein one of a large set of variable (V) genes combines with one of a smaller number of diversity (D) genes (in the immunoglobulin heavy chain) and joining (J) genes to produce the variable regions of both the heavy and light chains. The pairing of a heavy and light immunoglobulin chain in a random manner further expands the diversity of BCR on different B cells. Another limited set of genes encodes the constant (C) region of the immunoglobulin molecule. Although initially apart on the chromosome, the V(D)J complex is joined with a C region gene to produce the immunoglobulin heavy chain or light chain. The assembly of immunoglobulin genes depends upon two recombination activator genes, RAG-1 and RAG-2. After completion of the immunoglobulin gene arrangement, the BCR is expressed on the cell surface with a μ heavy chain, representative of the IgM class of antibody. As the cell continues its maturation, a second class of immunoglobulins, IgD, composed of the same V(D)J segment but a δ constant region gene, is also expressed at the B cell surface. Finally, the mature B cell completes recombination by secreting immunoglobulin products with the δ constant region (i.e., IgG antibodies), the α constant region (IgA antibodies), or the ϵ constant region (IgE) antibodies. Circulatory antibodies of the IgG class are

mainly responsible for acquired protective immunity; IgA antibodies produced at mucosal surfaces serve immune functions in secretions; IgE antibodies are associated with allergic and hypersensitivity reactions.

A small population of B cells, termed B-1 cells, develops early during ontogeny and expresses the CD5 cell surface marker. The cells secrete low- to moderate-affinity IgM antibodies that are often broadly cross-reactive, including reactions to common pathogens and self-antigens. The antibodies are referred to as natural antibodies because their production does not appear to require the presence of a specific antigen. They may provide some initial protection against infectious agents.

The mature B cell is activated by binding an antigen that expresses the complementary (cognate) epitope recognized by its BCR. The activation process requires cross-linking of membrane BCR. The receptor is associated with a number of auxiliary molecules such as CD19, CD20, and CD21, which act in concert with the receptor and serve as distinguishing markers of B cells. These molecules transmit activation signals to the interior of the cell after receptor aggregation takes place on the cell surface.

This event sets in motion a series of metabolic steps, manifest mainly by the activation of tyrosine kinases, leading to tyrosine phosphorylation of a set of substrates that control intracellular signals. Early events of activation lead to development from a resting mature B lymphocyte into a metabolically active B lymphoblast with enlarged cytoplasm containing multiple mitochondria. The B cell blasts then divide repeatedly to produce a clone, each member of which bears the parental BCR and, therefore, expresses the same epitope specificity.

Upon binding to the BCR, antigen is endocytosed and processed for presentation to specialized T cells (see below). In addition to presenting antigens, B cells secrete a number of cytokines such as IL-10, IL-12, tumor necrosis factor- α (TNF- α), and lymphotoxin, which subsequently act to direct or regulate immune responses (see **Cytokines**).

Some of the activated B cells differentiate into plasma cells, which are the source of circulating antibody, whereas others differentiate into memory cells, which give rise to memory response upon rechallenge of the individual with the same antigen. The hallmarks of the immune response are both its specificity for the antigen that induced its formation and the enhanced immune response or anamnestic response on rechallenge.

Since a single B cell bears multiple BCRs with identical specificities, cross-linkage of the receptors requires that an antigenic molecule express more than one identical epitope. A number of microbial

carbohydrates fulfill this requirement, and so B cells can be stimulated directly by the capsular polysaccharides of such microorganisms as pneumococci and meningococci. It is much less likely, however, that a globular protein will express more than one copy of an epitope. Under these circumstances, B cell activation requires help from a T cell capable of recognizing the same antigen. The endocytosed antigen is fragmented within the B cell, and the peptide fragments are loaded into the groove of a specialized cell surface glycoprotein, the class II major histocompatibility complex (MHC) molecule. The resultant class II/peptide fragment complexes are then inserted into the B cell surface. These complexes can be recognized by the antigen-specific receptors of the subset of T cells, referred to as CD4⁺ or helper T cells.

The two-way interaction between T cells and B cells is critical for the development of a vigorous, adaptive immune response. On the one hand, B cells concentrate antigens and effectively present them to T cells that recognize the particular antigen. On the other hand, activated CD4⁺ T helper cells produce cytokines that foster the activation and differentiation of B cells into plasma cells. When the T cell interacts with the MHC II/peptide fragment, it induces division of the B cell through the agency of costimulating surface molecules expressed by the T cell. CD154 of the T cell, for instance, engages CD40 of the B cell. In addition, T cell-derived cytokines, such as IL-4, IL-5, and IL-6, direct the B cell into an antibody-forming plasma cell. As the B cell progresses into the immunoglobulin-producing process, it undergoes a class switch; that is, the heavy chain C region, which originally expressed the specificities of the IgM and IgD classes, differentiates into cells that produce IgG, IgA, or IgE. This process allows the production of antibodies with differing biological functions while retaining the same antigen-combining site. At the same time, there is an increased affinity of the antibodies resulting from the extraordinarily high level of somatic mutation of the V genes, providing antibodies of high efficiency in combining with their antigenic targets.

T Lymphocytes

T lymphocytes constitute the second major class of lymphocytes, comprising approximately 70% of lymphocytes in the peripheral circulation and essentially all of the lymphocytes in the lymphatic circulation. They also derive from the hematopoietic stem cell through the lymphocyte progenitor, but undergo a process of differentiation in the thymus before they are seeded to peripheral lymphoid tissues and blood (see **Autotolerance**), (see **Thymus**). Like B cells,

mature T cells have a great diversity of antigen-specific cell surface receptors. T cell receptors (TCRs) are heterodimers made up of α and β chains or, rarely, γ and δ chains. Knowledge of the function of the latter subset of T cells is still limited.

Unlike the BCR, the TCR remains at the cell surface and is not shed into the medium. It is associated with a set of transmembrane proteins, referred to as the CD3 complex, which play a critical role in signal transduction. Through their agency, the T cell undergoes a process of activation similar to that described for the B cell. Like the BCR, the TCR is organized into a variable and constant portion. Furthermore, the same recombinational mechanisms are involved in the assembly of the V region genes in T cells and B cells. The process is controlled by RAG-1 and RAG-2, which together are required for T cell maturation. Antigen primed T cells may differentiate directly into effector or regulatory T cells. Following clonal expansion, a proportion of the antigen-stimulated T cells differentiates into long-lived memory cells. Memory T cells are responsible for the ability of the immune system to mount an anamnestic response when they encounter the same antigen. Thus, memory T cells play a central role in maintaining long-term protection against infection. In humans, memory T cells are usually CD45 RA⁻ CD45 RO⁺. Unlike effector T cells, they are not susceptible to programmed cell death following activation. Consequently, they survive for long periods of time in spleen and lymph nodes without undergoing division. Following a second encounter with their cognate antigen, memory T cells multiply rapidly and produce large amounts of cytokines so that even low levels of antigen can produce a vigorous secondary response. Memory B cells can be divided into central memory cells that inhabit secondary lymphoid organs and effector memory cells that migrate to inflamed areas.

T cells exert both regulatory and effector functions. The major regulatory T cells are the CD4⁺ helper T cells, referred to previously. Their regulatory function depends on costimulatory molecules, such as CD154, as well as the production of particular cytokines. Some CD4⁺ T cells develop into cells that primarily secrete the cytokines IL-4, IL-5, IL-6, and IL-13 (referred to as T_h2 cells) or into T cells that produce mainly IL-2, interferon- γ (IFN- γ), and lymphotoxin (referred to as T_h1 cells). The T_h2 cells help B cells to develop into antibody-producing cells, whereas T_h1 cells are primarily inducers of cell-mediated responses. Cell-mediated immunity is responsible for protection against intracellular microorganisms and involves the activation of macrophages as well as the generation of cytotoxic T cells. Cytotoxic T cells mediate the direct killer functions

of cell-mediated immunity; they carry the CD8 marker in place of CD4 and are capable of lysing target cells that express the requisite antigen together with matched class I MHC. Virus-infected tissue cells, for example, may be eliminated from the host's cells by virus-specific CD8 T cells.

Under normal circumstances, the immune system is kept under strict control by a variety of regulatory mechanisms. Regulatory or suppressor T cells were recognized a number of years ago, but their identity remained elusive. Recently, several populations of T cells with regulatory capability have been identified. They include naturally occurring T regulatory cells (Tregs), which were first identified by their ability to prevent spontaneous autoimmune disease. They are characterized by the cell surface marker CD4⁺CD25⁺ and the transcription factor FoxP3. The critical role of the FoxP3 factor is attested by the demonstration that CD4⁺CD25⁺ T cells do not develop a regulatory function in FoxP3-deficient mice. In addition, retroviral transduction of FoxP3 into CD4⁺CD25⁻ cells converts them into functional regulatory T cells. CD4⁺CD25⁺ Tregs are anergic *in vitro*, failing to proliferate following nonspecific or antigen-specific stimulation. They can, however, mount an antigen-dependent proliferative response *in vivo*. The T cell growth factor IL-2 appears to play a critical role in their development, since mice genetically deficient in IL-2 have reduced numbers of Tregs. The distinguishing feature of Tregs is their ability to suppress a broad range of innate and adaptive immune responses; the suppression requires direct contact between the regulatory T cell and its target.

In addition to naturally occurring Tregs, naive T cells can be induced to differentiate into regulatory T cells following an encounter with their cognate antigen. These cells differ from the natural CD4⁺CD25⁺ Tregs in that they do not express FoxP3 and act primarily by the production of immunosuppressive cytokines such as IL-10 and transforming growth factor- β (TGF- β). They are referred to as Tr1 cells. These induced regulatory T cells are favored by antigen presentation through immature dendritic cells or by environments in which high levels of suppressive cytokines are present, such as at mucosal surfaces. Because induced Tr1 cells secrete these immunosuppressive cytokines, they can downregulate responses to other nearby antigens, a process called bystander suppression.

Recent studies have provided evidence of a number of other regulatory T cell populations. For example, CD8⁺ T cells can mediate immune regulatory functions including allograft rejection. Although their

mechanism of action is still unclear, they may induce suppression by cytolysis of helper CD4⁺T cells.

NKT cells represent a distinct lineage of T cells that are characterized by an invariant TCR light chain as well as by the presence of characteristic NK cell markers. This invariant TCR does not recognize peptide presented in the usual fashion by class I or class II MHC molecules, but instead recognizes lipids and glycolipids presented by the nonclassical CD1 molecule. It appears that NKT cells are capable of both upregulating and downregulating immune responses.

Finally, a population of regulatory T cells bearing the CD3⁺ marker but lacking CD4⁺ or CD8⁺ has been described. The cells are referred to as double-negative T cells, but their mode of action is still unknown.

T cell recognition differs from that of B cells. The BCRs recognize free antigens based on their complementary conformations. In contrast, T cells respond to antigens only on the surface of other cells, because they recognize the complex of a peptide fragment bound in the groove of a class II or class I MHC glycoprotein. CD4⁺ T cells recognize peptides in class II MHC complexes, whereas CD8⁺ T cells recognize peptides in class I complexes. In the case of class II recognition, the MHC/peptide fragment complex is generated within an antigen-presenting cell (APC). They may be B cells, as described previously, macrophages, interdigitating dendritic cells of the lymph nodes, circulating dendritic cells, or Langerhans cells of the skin (see **Lymph Nodes**). In all of these cells, endocytosed proteins are fragmented by proteolytic enzymes within the endosomal/lysosomal compartment, and the resulting short peptides are loaded into the class II MHC groove. The complexes are then expressed at the surface of the cell, where they can be recognized by those CD4⁺ T cells that bear the requisite TCR. The recognition is based not on the conformation of the antigen, but rather on key amino acids.

CD8⁺ T cells recognize antigens and peptides in conjunction with class I MHC molecules. Generally, these antigens are derived from internally synthesized proteins, including viral proteins (see **Herpesviruses**). The fragments are produced in cytoplasmic vesicles by proteolysis, translocated into the endoplasmic reticulum, and bound to the class I MHC molecules, which are then brought to the cell surface. There they can be recognized by CD8⁺ T cells expressing the appropriate receptors. Generally, the antigenic epitopes loaded into class I MHC are approximately nine amino acids in length.

Two signals, specific and nonspecific, are required for T cell activation. Specificity is provided by the

interaction of the TCR with an MHC/peptide fragment complex. A second, non-antigen-specific costimulating signal is given by membrane glycoprotein of the APC B7-1 (CD80) or B7-2 (CD86). Through their interaction with CD28 on resting T cells, these molecules trigger activation and clonal expansion of the T cell. Engagement of the TCR in the absence of B7 costimulation results in clonal anergy. Another receptor expressed on activated T cells, CTLA-4, binds B7 and may serve as a regulatory signal.

A number of other costimulatory receptors have recently been described, including inducible costimulator intracellular (ICOS) and programmed death-1 (PD1), which regulate the immune response.

Natural Killer (NK) Cells

NK cells are an important component of the innate as well as the adaptive immune system. In fact, in animals that lack the RAG-1 or RAG-2 genes, NK cells provide a substantial degree of protection against infection. They comprise about 10% of the circulating lymphocytes. Although closely related to T cells, they lack the conventional TCRs, but express two specialized receptors. One receptor allows them to recognize virally infected cells or tumor cells, permitting them to destroy such cells. They also express receptors for the host's class I MHC molecules, which inhibit lytic activity. Thus, the NK cell is disarmed in the presence of its corresponding MHC molecule. Often, tumor cells or virally infected cells diminish expression of class I MHC molecules, thus avoiding the attack of cytotoxic T cells. They may then become targets for killing by NK cells, which are no longer shut off by recognition of the host MHC class I molecules. In addition, some NK cells express receptors for the constant portion of the immunoglobulin molecule. Armed with an IgG, the NK cell then has acquired a specific receptor to direct its cytotoxic effects, lysing target cells that bear the appropriate antigen. This process is referred to as antibody-dependent, cell-mediated cytotoxicity (ADCC). Thus, the NK can mediate its cytotoxic actions through two different recognition mechanisms. NK cells also produce cytokines that regulate the development of acquired immunity, for example, IFN- γ , and stimulate macrophages to produce cytokines, such as TNF and

IL-12, which enhance the development of cell-mediated immune responses.

Introduction

Stress Influences Mycobacterial Infection

Summary

Glossary

Nramp (*natural resistance associated macrophage protein*) A phagolysosomal membrane product encoded by the *Nramp1* gene that confers resistance to mycobacterial growth during the early nonimmune phase of infection. Susceptible mice differ from resistant mice in a nonconservative glycine-to-aspartic acid substitution within a predicted transmembrane domain of Nramp1.

Introduction

Tuberculosis, a worldwide public health problem, has also increased significantly in the United States. The increase in tuberculosis is partly due to depressed cellular immunity associated with HIV infection. However, tuberculosis has also increased independently of HIV infection. Only since 1997, following mobilization of the public health community, has the incidence of tuberculosis in the United States begun to resume its downward course. Tuberculosis is a highly complex disease with multiple determinants for disease progression and severity. The susceptibility of humans to mycobacterial disease is determined partly by genetic

differences. One of the most important genetic factors determining resistance to mycobacterial infection is the ability of host macrophages to control the growth of the tubercle bacilli.

Innate Resistance against Mycobacteria

The innate resistance of macrophages to mycobacterial infection has been studied most thoroughly in mice. The ability of mice to control mycobacterial growth in the spleen, following intravenous injection of *Mycobacterium bovis* BCG, maps to a region on mouse chromosome 1. Mice resistant to mycobacterial growth are termed Bcg^r, whereas those strains in which mycobacteria grow exponentially are termed Bcg^s. The resistance of Bcg^r mice is mediated by the *Nramp1* gene, which has been cloned in both mice and humans. *Nramp1* codes for a phagolysosomal membrane product termed natural resistance associated macrophage protein. Susceptible mice differ from resistant mice in a nonconservative glycine-to-aspartic acid substitution within a predicted transmembrane domain of Nramp1. While the mechanism of Nramp-mediated resistance remains ill defined, work from the authors' laboratory suggests that Nramp1 acts as a transporter of iron into the macrophage phagolysosome.

Although the susceptibility of an individual to mycobacterial disease is influenced strongly by innate immunity, genetic differences alone cannot account for the recent rise in the incidence of tuberculosis. The vast majority (90–95%) of people exposed to pathogenic strains of mycobacteria are able to control the growth of the organism without any disease manifestations. While some macrophages are able to limit mycobacterial growth, they are not sufficient to resolve a primary mycobacterial infection. Fortunately, macrophages are the major antigen-presenting cells of the body. Enzymes in the macrophage phagolysosome digest microorganisms killed by the respiratory burst and some microbial peptides become associated

with glycoproteins encoded by genes of the major histocompatibility complex (MHC). Peptides coupled to MHC class II glycoproteins are cycled to the cell surface where they serve as the sole basis for antigen recognition by CD4⁺ T lymphocytes. These macrophages then travel to regional lymph nodes where they present this processed antigen to T cells.

Specific Immune Response to Mycobacterial Infection

T-cell activation results in the development of cell-mediated immunity and enhanced reactivity to the purified protein derivatives (PPD) of mycobacteria. Activated Th cells then travel to the area of the primary focus and release lymphokines that cause monocytes to migrate into the site and differentiate into specialized histiocytic cells termed epithelioid giant cells. The primary lesion becomes organized into a granuloma, with macrophages containing ingested mycobacteria located centrally surrounded by epithelioid giant cells and activated T cells. The production of interferon (IFN)- γ by activated T cells results in macrophage activation and enhanced antimicrobial activity resulting from the activation of IFN- γ responsive genes. Mycobacteria may persist within macrophages of the granuloma for decades, but in immunocompetent individuals, further multiplication and spread are usually confined. The relative strength of the cell-mediated immunity of the host ultimately determines if resumption in multiplication of the mycobacteria will occur. The consequence of a resumption in the multiplication of bacilli leads to tuberculosis with subsequent tissue destruction, systemic dissemination of disease, and, when left untreated, death. Reactivation of disease has been attributed to several environmental factors, including protein malnutrition associated with chronic alcoholism, immunosenescence associated with aging, and stress.

Stress Influences Mycobacterial Infection

One of the first observations that stressful life events can affect disease pathogenesis was made in studies of tuberculosis by Ishigami. Ishigami found decreased phagocytic cell activity during periods of emotional stress in chronically ill, tuberculous school children. He postulated that the stressful school environment led to the children's immunodepressed state and their increased susceptibility to tuberculosis. Contemporaneous studies have proven that physical and psychological stress can modulate susceptibility to tuberculosis as well as general immune function. Physiologic responses to stressors are mediated by

both the hypothalamic-pituitary-adrenal (HPA) axis and the sympathetic nervous system (SNS).

HPA Axis Effects on Mycobacterial Infection

The HPA axis mediates the stress response by producing a cascade of hormones in response to a variety of stimuli, ultimately resulting in the enhanced production of glucocorticoids by the adrenal glands. Glucocorticoids then enter the circulation and exert their effects through binding to cytoplasmic receptors. Upon binding, the glucocorticoid-receptor complex is internalized and translocated to the nucleus where it binds to glucocorticoid response elements (GREs). The receptor-charged GREs enhance the transcription initiation of glucocorticoid-regulated genes influencing the amount of critical proteins within the cell. Glucocorticoids have been shown to suppress the immune response. Glucocorticoid hormones cause a species- and cell type-specific lysis of lymphocytes. They suppress the inflammatory response by decreasing the number of circulating leukocytes and the migration of tissue leukocytes, inhibiting fibroblast proliferation, and inducing lipocortins that blunt the production of prostaglandins and leukotrienes, which are potent anti-inflammatory molecules.

Mononuclear cells possess high-affinity (type II) glucocorticoid receptors and represent one of the best studied primary target cells for glucocorticoids. Studies have shown that the production of proinflammatory cytokines interleukin (IL)-1, IL-6, and tumor necrosis factor (TNF)- α by activated macrophages is blocked at the transcriptional and posttranscriptional level by glucocorticoids. The downregulation of these potent mediators of inflammation underlies some of the immunosuppressive and anti-inflammatory actions of glucocorticoids, but does not address the effect glucocorticoids have on macrophage-T-cell interactions. Due to the requirement for macrophage MHC class II expression in antigen presentation for the induction of an immune response, the authors began their work by evaluating the effect of restraint stress on the expression of MHC class II glycoprotein expression in murine macrophages.

MHC class II glycoprotein expression is induced in mice following the injection of antigen or microorganisms *in vivo* or by treatment of macrophages with recombinant IFN- γ *in vitro*. It was found that macrophages from resistant strains of mice are able to persistently express MHC class II following infection of the mice with *M. bovis* (strain BCG). It was shown subsequently that the treatment of macrophages from Bcg^r mice with rIFN- γ induced persistent MHC class II expression, whereas macrophages from

Bcg^s mice expressed this glycoprotein only transiently. The regulation of MHC class II expression by macrophages from resistant and susceptible mice also differed. Glucocorticoid treatment of macrophages from susceptible mice resulted in decreased MHC class II expression, whereas MHC class II expression by macrophages from resistant mice was unaffected.

The regulation of MHC class II expression by glucocorticoids raised the possibility that stress could modulate class II expression following activation of the HPA axis. This hypothesis was confirmed by demonstrating that restraint stress suppressed MHC class II expression by murine peritoneal macrophages and that this suppression coincided with peak corticosterone levels in plasma. The authors' previous work that showed strain-specific differences in MHC class II glycoprotein expression was extended by showing that the stress-induced suppression of MHC class II expression was limited to certain strains of mice. Bcg^r mice were resistant to the restraint stress-induced decrease in MHC class II glycoprotein expression observed in Bcg^s mice. The resistance of Bcg^r mice was not due to a decrease in HPA axis activation, as corticosterone suppressed the induction of MHC class II by macrophages from both resistant and susceptible mice.

Adrenalectomy ameliorated the suppressive effects of restraint stress on MHC class II expression in Bcg^s mice by abrogating the increase in corticosterone that results from HPA axis activation. Later experiments showed that the difference in MHC class II expression by macrophages from resistant and susceptible mice was due to a difference in MHC class II mRNA stability (Figure 1). Corticosterone decreased the stability of MHC class II mRNA in macrophages from susceptible mice but not in macrophages from resistant mice. The stability of mRNA of other IFN- γ -induced genes was affected similarly. Thus, the increased mRNA stability of macrophages from Bcg^r mice may account for the pleiotrophic effects that have been attributed to *Nramp1*.

The differential regulation of MHC class II glycoprotein expression by glucocorticoids could account for differences in tuberculosis susceptibility. The role of HPA axis activation in the control of the growth of mycobacteria in humans has been the subject of some discussion. Glucocorticoid treatment of human macrophages suppressed antimicrobial activity markedly. However, Rook and co-workers showed that dexamethasone increased the susceptibility of monocytes from some individuals to mycobacterial growth, but other donor monocytes were unaffected by glucocorticoid treatment.

Figure 1 Stabilized expression of mRNA is associated with mycobacterial resistance controlled by *Nramp1*. Splenic macrophages from Bcg^r and Bcg^s mice were stimulated with rIFN- γ for 24 h followed by treatment with corticosterone. After 20 h, total RNA was extracted, and the effect of corticosterone on the expression of rIFN- γ -induced genes was determined by Northern analysis. These studies, together with previous work on MHC class II expression, led the authors to conduct a series of experiments to determine if mycobacterial growth, which is under *Nramp1* control, may also be affected differentially by HPA axis activation. It was found that activation of the HPA axis increased the growth of mycobacteria in susceptible mice but did not affect the ability of resistant mice to limit growth of the bacilli (Figure 2). The failure of restraint stress to increase the susceptibility of Bcg^r mice was not due to unresponsiveness of this strain of mouse to HPA axis activation. HPA axis activation resulted in an increase in plasma corticosterone and ACTH levels in both strains of mice. The role of corticosterone in mediating the effects of HPA axis activation was demonstrated in three ways. First, adrenalectomy abolished the effect of HPA activation on mycobacterial growth. Second, treatment of Bcg^s mice with the glucocorticoid receptor antagonist RU 486 abrogated the effects of restraint stress. Finally, the implantation of timed-release pellets that elevated plasma corticosterone levels to those attained by restraint increased the growth of mycobacteria in adrenalectomized susceptible mice. A subsequent *in vitro* study of macrophages

Figure 2 Regulation of mycobacterial growth by the hypothalamic-pituitary-adrenal axis: differential responses of *Mycobacterium bovis* (strain BCG)-resistant and -susceptible mice. Mice were restrained for ten 18-h cycles after infection with 5×10^4 CFU of *M. avium*. The numbers of CFU in the spleens were determined 12 days after infection. Data are the means $\pm$ SD for seven animals per group. The difference between growth of mycobacteria in the spleens of Bcg^r (■) mice versus growth in those of Bcg^s (▨) mice was significant ($P < 0.001$). from Bcg^r and Bcg^s mice showed that corticosterone addition decreased the antimycobacterial activity of susceptible macrophages, whereas corticosterone had no effect on resistant macrophages (Figure 3).

Sympathetic Nervous System Effects on Mycobacterial Infection

Stress results in activation of the HPA axis as well as the SNS. The authors have also reported that epinephrine treatment of peritoneal macrophages suppressed MHC class II expression induced by rIFN- γ . Other observations found that restraint stress also increased epinephrine and norepinephrine levels in the spleen. Numerous other studies have reported that macrophage function can be suppressed or stimulated by catecholamines. It was found that catecholamine treatment of macrophages infected with mycobacteria inhibited intracellular growth of the bacilli. By using specific adrenoceptor agonists and antagonists, it was shown that this effect of catecholamines was mediated via the α_2 -adrenergic receptor. The mechanism that accounts for this stimulation of macrophage functional capacity by catecholamines is under investigation. The use of macrophages harvested from Bcg^s mice in this study demonstrates that susceptible macrophages can be induced to control mycobacterial growth.

It has been reported that epinephrine treatment of *Mycobacterium avium*-infected macrophages increased IL-10 production. This effect was mediated by the β_r -adrenoceptor and could be mimicked by the addition of cAMP. IL-10 is a cytokine produced by a

Figure 3 Cytokine-mediated activation of macrophages from *Mycobacterium bovis* (strain BCG)-resistant and -susceptible mice: differential effect of corticosterone on antimycobacterial activity and expression of the *Nramp1* gene. Splenic macrophages were treated with rIFN- γ for 24 h prior to infection with 4×10^5 CFU of *M. avium*. After 24 h to allow for phagocytosis and following removal of unphagocytized bacteria, the cultures were treated with 10^{-6} M corticosterone + rIFN- γ or just rIFN- γ for 5 days prior to lysis of the macrophages and pulsing of the bacteria with [³H] uracil. Data are expressed as the percentage of the control value, which represents the amount of radioactivity incorporated by the bacteria after infection of cultures of macrophages treated with rIFN- γ divided by that of cultures not treated with rIFN- γ . The effect of corticosterone on the antimycobacterial activity of rIFN- γ -activated macrophages from Bcg^s mice was significant ($P \leq 0.03$). variety of immune cells that has a diverse array of actions. IL-10 production could play a role in tuberculosis by affecting the production of IFN- γ by T cells. IL-10 has been shown to inhibit MHC class II expression on monocytes and to inhibit T-cell proliferation directly. Preliminary studies in the authors' laboratory have also found that catecholamine treatment can inhibit macrophage activity. It has been shown that the addition of catecholamines during the infection of rIFN- γ -primed macrophages reduced reactive nitrogen intermediate production. Studies on the regulation of catecholamine-induced modulation of macrophage function are currently underway.

Summary

Differences in the resistance of certain mouse strains to mycobacterial growth have allowed us to study the effect activation of the HPA axis has on the innate mechanisms of mycobacterial resistance. It has been shown that macrophages from *M. bovis* BCG-resistant and -susceptible mice differ in their susceptibility to HPA axis-mediated effects. MHC class II glycoprotein expression by macrophages from Bcg^s mice decreased in response to increased plasma corticosterone levels

induced by restraint. Restraint of Bcg^r mice led to a similar rise in corticosterone levels, but MHC class II expression remained unaffected. Restraint stress also increased mycobacterial growth in susceptible mice but did not affect the ability of resistant mice to limit growth of the bacilli. These results suggest that activation of the HPA axis may account for the increase in susceptibility of Bcg^s mice to mycobacterial growth. This suppression may be particularly apparent in individuals who express the mutation in *Nramp1* that results in susceptibility to mycobacterial disease and may account for the increase in the incidence of active tuberculosis among susceptible populations. Other work in the authors' laboratory has shown that catecholamine treatment of susceptible macrophages increased their ability to inhibit the intracellular growth of mycobacteria. The significance of these findings to mycobacterial disease is under investigation.

Origin and Function of Monocytes/Macrophages
Stress and Monocytes/Macrophages

Glossary

Activated macrophage

A macrophage that has been stimulated either biochemically or immunologically and exhibits an increase in one or more functional activities or the appearance of a new functional activity.

Cytokines

A class of low-molecular-weight soluble protein molecules released by immune cells during the course of immune response that serve to mediate and regulate the amplitude and duration of immune/inflammatory responses in the organism. Cytokines are produced during the effector phases of natural and specific immunity in a brief self-limited event. Many of the same cytokine substances are produced by different cells and may act on

many different cell types. Cytokines exert their action by binding to target cell-surface receptors, which may be on the surface of the secreting cell (autocrine action), on the surface of a nearby cell (paracrine action), or on the surface of a cell in a remote location (endocrine action) reached through the bloodstream. Cytokines that are principally synthesized by leukocytes and act primarily on leukocytes.

Large, irregularly shaped white blood cells measuring 25–50 μm in diameter that are the major differentiated cells of the mononuclear phagocyte system.

A class of immune cells that have a common lineage that includes monoblasts, promonocytes, monocytes, and macrophages.

A G-protein-coupled receptor that mediates the biological responses to substance P that has been demonstrated on T cells, B lymphocytes, neutrophils, mast cells, and monocytes/macrophages.

An 11-amino-acid peptide present in the central nervous system that is involved in the pathogenesis of nausea/emesis, pain, mood disorders, stress, anxiety, reinforcement, neurotoxicity, and neurogenesis. It is a member of the tachykinin family of neuropeptides. Outside the central nervous system, SP regulates intestinal motility and secretion, causes vasodilation, and serves as a modulator of a number of important immunological functions. Circulating levels of SP become elevated in stressful situations; monocytes stimulated

Interleukins (ILs)

Neurokinin (NK-1) receptor

Substance P (SP)

Tissue macrophages

by SP produce and release cytokines such as tumor necrosis factor α , interleukin-1, and interleukin-6.

Members of the monocyte/macrophage family that have migrated from the circulation into a body tissue, remaining adherent for several months and ultimately migrating to nearby draining lymph nodes for disposal at the end of their useful life. Some tissue macrophages may survive for the lifetime of the individual.

Macrophages are a diverse group of leukocytes (white blood cells) that share a common origin in the bone marrow and enter the circulation as incompletely differentiated monocytes. Macrophages are the major differentiated cells of the monocyte/macrophage system.

Origin and Function of Monocytes/Macrophages

The monocyte/macrophage system comprises bone marrow monoblasts and promonocytes, peripheral blood monocytes, and tissue macrophages. The peripheral blood monocytes differentiate into macrophages that are capable of phagocytosis of particles, cells, bacteria, and fungi; they also have major roles in antigen presentation and cytokine secretion. Monocytes remain in the circulatory system or migrate to different tissues where they increase in size, becoming tissue macrophages. Tissue macrophages become part of the architecture of specific tissues where they may remain, performing specific protective functions and functions unique to the organ. These tissue macrophages are given names according to their location (Table 1). Tissue macrophages may be stimulated by chemical messengers to break away from their attachment and migrate along with mobile macrophages and monocytes to areas of inflammation by

a process known as chemotaxis. The term monocyte/macrophage system is virtually synonymous with, and has replaced in the nomenclature, the reticulo-endothelial system.

Macrophages perform an essential function in the immune system by attacking and destroying invading bacteria, viruses, and other injurious substances, participating in a wide range of physiological and pathological processes. Although many micro-organisms are phagocytized and destroyed with ease by macrophages, certain pathogens such as listeria, salmonella, brucella, mycobacteria, chlamydia, rickettsia, leishmania, toxoplasma, trypanosoma, and legionella are able to parasitize nonactivated macrophages and replicate within them. Only when macrophages have been activated against these specific intracellular pathogens are they able to inhibit or destroy them. Monocytes and macrophages play an active role in the clearance and inactivation of most viral pathogens. Paradoxically, these same cells also represent a major target cell and infectious reservoir for many viruses. The human immunodeficiency virus (HIV-1) infects and replicates within monocytes and macrophages by binding to the CD4 and CCR5 receptors that are present on the macrophage cell membrane.

The macrophages in tissues and body cavities are a cell population that is regularly renewed by the influx of monocytes manufactured in the bone marrow and circulated via the blood. The control of monocyte production, release of monocytes into the blood, monocyte migration and extravasation into tissues, and finally differentiation into tissue macrophages are accomplished by means of soluble chemical factors. These soluble chemical factors are termed cytokines and are themselves influenced by stress-associated factors such as adrenocorticotrophic hormone (ACTH), cortisol, adrenergic hormones, and neuropeptides such as substance P (SP), vasoactive intestinal peptide (VIP), and proopiomelanocortin (POMC). Macrophages secrete cytokines that produce effects on other immune cells, as well as receptors for cytokines produced by other immune cells, thereby promoting bidirectional communication. The major cytokines that produce effects on the monocyte/macrophage cells are: interferon (IFN- γ), IFN- α , IFN- β , and interleukin (IL-1). Monocyte/macrophages produce and secrete IL-1, IL-6, and tumor necrosis factor (TNF- α).

Phagocytosis and Microbicidal Functions

The term macrophage was first used more than 100 years ago by Elie Metchnikoff to describe the large mononuclear phagocytic cells he observed in tissues. Through the process of phagocytosis, macrophages are

Table 1 Tissue-localized macrophage/monocyte cells

Location	Cell type
Bone marrow	Monoblasts, promonocytes, monocytes, macrophages
Peripheral blood	Monocytes
Skin	Langerhans cell and histiocyte
Lung	Alveolar macrophage
Bone	Osteoclast
Liver	Kupffer cell
Central nervous system	Microglia
Lymphoid organs	Tissue macrophages, dendritic cells
Spleen	Red-pulp macrophages
Gastrointestinal tract	Tissue macrophages
Serous cavities	Pleural and peritoneal macrophages

one of the most effective components of nonspecific immunity. Macrophages also play two essential roles in specific immunity, first as professional antigen presenting cells and then, with proper stimulation, as immune effector cells. Once activated by the immune system, macrophages become more powerful than neutrophils in their ability to phagocytize. Macrophages are able to engulf much larger particles such as whole red blood cells and malarial parasites or as many as 100 bacteria. Phagocytized particles are encapsulated and digested by intracellular proteolytic enzymes contained in lysosomes and other cytoplasmic granules. Macrophage lysosomes are unusual in that they contain lipases that aid in the digestion of the thick lipid bacterial membranes. Once the engulfed particles are digested, macrophages can extrude residual products. Macrophages perform many essential roles in the immune response such as the direct killing of damaged cells, bacteria, and viruses and antigen presentation. Macrophages produce and respond to cytokines and other chemicals central to both the inflammatory and the specific immune response. There are populations of macrophages that live throughout the life span of the organism.

Cytokine Mediation of Macrophage Response

Macrophages express major histocompatibility complex (MHC) class II on their surface and are important antigen-presenting cells for both B and T lymphocytes. Macrophages, when activated by cytokines produced by T helper (TH) cells, become effector cells of cell-mediated immunity. Macrophages are the first cells involved in an immune reaction and help orchestrate immune events both by the production of chemical signals (cytokines and SP) and by the processing and presentation of antigens to subsets of T lymphocytes that may either enhance or suppress specific immune responses. Activated macrophages also produce cytokines, such as IL-1, TNF- α , and IL-6, that augment T-cell function, as well as IL-8, macrophage colony-stimulating factor (M-CSF), granulocyte macrophage colony-stimulating factor (GM-CSF), and granulocyte colony-stimulating factor (G-CSF) that stimulate polymorphonuclear neutrophil (PMN) and monocyte activity. The ability of macrophages and lymphocytes to stimulate one another's functions provides an important amplification mechanism for specific immunity. Thus, macrophages play an important and central immunoregulatory role.

Toll-like Receptors

Toll-like receptors, identified in macrophages in mammals, are a relatively new family of membrane receptors able to recognize specific patterns of pathogen

components, such as bacterial endotoxins and viral nucleic acids. Toll-like receptor (TLR)-4 is part of a molecular complex that recognizes and mediates intracellular responses to lipopolysaccharide (LPS). Pathogen recognition by TLRs activates the innate immune system through different signaling pathways, causing inflammatory responses such as cytokine production. Impaired adrenal stress response occurs in TLR-2-deficient mice, suggesting that TLR-2 and, possibly, TLR-4 may constitute an important link between the immune and endocrine stress systems at both the central and peripheral levels, particularly during inflammation and sepsis.

Stress and Monocytes/Macrophages

An examination of the role of macrophages in the modulation of immune function by stress is particularly compelling. A representation of the interactions among various stressors and the immune system is provided in [Figure 1](#).

Macrophages play a pivotal role in immune responses, first as professional antigen-presenting cells stimulating the expansion of one of two sets of CD4⁺ T-cell populations (TH1 or TH2) and finally, when activated themselves, functioning as major effector cells in cell-mediated immunity. The TH1 and TH2 responses are highly integrated and contraregulated, relying on two distinctly different profiles of cytokine production. Many of the cytokines produced by one or the other subpopulation have positive effector functions and, in addition, negatively regulate the activity of the alternate subgroup. The negative regulation may be at the level of either T-cell expansion or T-cell effector functions, including macrophage activation. Thus, an immune response in which TH1 cells are stimulated downregulates the co-stimulation of TH2 cells. Conversely, an immune response in which TH2 cells are stimulated downregulates both the co-stimulation of TH1 cells and their effector activity.

TH1 cells produce cytokines associated with aspects of classic cell-mediated immunity, producing IFN- γ , IL-2, IL-3, GM-CSF, TNF- α , and TNF- β , which activate macrophages. IFN- γ induces oxygen burst and nitric oxide production, which are essential for microbicidal reactions. IL-3 activates macrophages, causing increased antigen presentation. IFN- γ and IL-2 both stimulate macrophages to produce TNF- α , which in turn further stimulates macrophage activation in a cascade of events.

TH2 cells produce cytokines (IL-4, IL-5, and IL-6) that are associated with the B-cell responses of humoral immunity. IL-4 acts as a growth factor specific for TH2 cells, acts as an inhibitory factor for the

Figure 1 Stress effects on monocyte/macrophages. The effects of stress on the immune system are mediated by the neuropeptide substance P. The cells of the monocyte/macrophage system have receptors for and are able to synthesize and release substance P. Thus, they play a central role in mediating these effects. CNS, central nervous system; GM-CSF, granulocyte macrophage colony-stimulating factor; IFN, interferon; IL, interleukin; PNS, peripheral nervous system; TNF, tumor necrosis factor.

stimulation of TH1 cells by IL-2, and also effectively inhibits IFN- γ activation of macrophages. When appropriately stimulated by TH2 cytokines and antigen, B cells give rise to antibody-secreting plasma cells. The antigen-antibody complex serves as a powerful stimulator of the monocyte/macrophage phagocytosis of these circulating complexes.

In a mouse surgical-sponge model of inflammation, acute restraint-induced stress caused increase in leukocyte trafficking to the site of immune activation. Mice acutely stressed before sponge implantation presented 200–300% higher macrophage, neutrophil, natural killer cell, and T-cell infiltration than did nonstressed animals. Stress-induced increases in leukocyte trafficking may be responsible for immunoprotection during trauma, surgery, and infection, but it may also exacerbate immunopathological responses during inflammatory diseases, such as arthritis, cardiovascular disease, psoriasis, multiple sclerosis, and gingivitis.

Substance P as a Mediator of Stress Response

A major mediator of the effects of stress on monocyte/macrophage function is the neurotransmitter peptide SP, which is widely distributed in the central, peripheral, and enteric nervous systems. SP may have a major role in several inflammatory disease processes such as rheumatoid arthritis, bullous pemphigus, asthma, and inflammatory bowel diseases such as Crohn's disease and ulcerative colitis, as well as in the transmission of pain. SP may be the chemical messenger of a neurogenic alarm system that serves to communicate stress in a reciprocal manner among the central nervous system (CNS), endocrine system, and immune system. SP is associated with the sympathetic nervous system and is essential to the maintenance of adrenal catecholamine secretion from the adrenal medulla in times of stress.

Studies of surgical patients demonstrate that the stress of surgery shifts the TH1/TH2 cytokine balance

toward TH2, suggesting that cell-mediated immunity was downregulated. Furthermore, the highest immune alteration was associated with the most stressful and invasive surgery. Several experimental animal studies indicate an association between stress and levels of SP. Two studies of SP in the brain tissue of rats that had been subjected to stressful stimuli found decreases in SP levels, which the authors attributed to tissue SP depletion following the increased release of SP. Experimental models of induced stress such as restraint stress and sequential removal of group-housed rats were found to be associated with increased levels of SP in the periaqueductal gray area of the brain. Insulin-induced hypoglycemia or mild electric foot shock were shown to increase the release of both catecholamines and SP from rat adrenomedullary cells. The intracerebroventricular administration of SP in conscious rats elicited an integrated cardiovascular, behavioral, and endocrine response in a pattern consistent with an integrated stress response in rodents. Experimental evidence in first-time parachutists and patients undergoing diagnostic procedures demonstrated increased levels of circulating SP associated with acute psychological stress. The high levels of circulating SP remained elevated long after the anxiety associated with the acute stressor diminished.

Macrophages, endothelial cells, eosinophils, and Leydig cells have also been identified as nonneuronal sources of SP. The presence of specific SP receptors on the surface of monocytes and the ability of macrophages to produce SP suggest its role in the autocrine regulation of SP gene expression.

The biological responses to SP are mediated by the NK-1 receptor, a 407-amino-acid G-protein-coupled glycosylated receptor that has been demonstrated on T cells, B lymphocytes, monocytes, macrophages, neutrophils, and mast cells. There is a connection between SP in the peripheral nervous system and the immune system. There is direct innervation of the spleen by SP-containing nerve fibers in splenic areas adjacent to lymphocytes, macrophages, and granulocytes, with evidence of its role in the traffic of lymphocytes from lymph nodes. SP modulates the effector phase of adaptive immunity and serves as a co-stimulator in the activation of monocytes, macrophages, T cells, and B cells, with the subsequent release of regulatory cytokines by these cells.

Effect of Stress on Monocytopoiesis

Macrophages synthesize and release two hematopoietic growth factors, M-CSF and GM-CSF, in response to external stimuli such as particles that are phagocytosed and endotoxin. Furthermore, macrophages

release IL-1 and TNF, which in turn can induce fibroblasts and endothelial cells to produce M-CSF and GM-CSF, which stimulate the production of mononuclear phagocytes. The spiral of increased inflammatory response is further magnified by the synthesis of TNF- α by mononuclear phagocytes in response to GM-CSF stimulation. Thus, macrophages play a pivotal role in regulating immune response. SP induces the production of hematopoietic growth factors IL-1, IL-6, and TNF- α from human monocytes. Bone marrow is innervated by nerve fibers that release SP in concentrations that induce tissue macrophages resident in bone marrow to release IL-1, IL-3, and GM-CSF.

Furthermore, macrophages express NK-1 receptors and serve as a nonneuronal source of SP. The release of SP by macrophages serves as a paracrine mechanism (by stimulating nearby macrophages) for amplifying the effect of stress on monocytopoiesis. Thus, stress acting through SP as a mediator may play a physiological role in regulating monocytopoiesis through two mechanisms: stimulation of the direct release of hematopoietic growth factors by monocytes and paracrine amplification.

Effect of Stress on Monocyte/Macrophage Function

The manner and extent to which stress influences immune response is, then, of vital concern. Stress may either enhance or inhibit macrophage function. Experimental evidence shows that SP plays a role in modulating immune response at each of the succeeding levels of response to foreign antigen. SP induces the release of stem cell factor and IL-1 in bone marrow stroma, thereby mediating hematopoiesis. A summary of the effects of stress on the monocyte/macrophage system is provided in [Table 2](#).

During acute inflammatory reactions, the number of circulating monocytes is increased with enhanced bone marrow production. This is mitigated by the decreased time that the monocytes are in the circulation due to efflux into inflammatory exudates. The SP-containing neurons have direct contact with immune and hematopoietic cells in the primary and secondary lymphoid organs. Thus, traffic of lymphocytes may be regulated by the secretion of neuroactive peptides such as SP from nerves.

Macrophages and monocytes increase phagocytosis and increase chemotaxis in response to SP. Increased levels of IL-6 are released by peritoneal macrophages in response to increased levels of SP produced by mice exposed to cold-water stress. Macrophages from humans and guinea pigs have receptors for and respond to SP-releasing cytokines

Table 2 Effects of stress on monocytes/macrophages

Source	Model	Effect
Animal (<i>in vitro</i>)	Macrophages exposed to salmonella	Increased SP receptors
Animal (<i>in vivo</i>)	Mice exposed to salmonella given SP antagonist	Increased mortality
	Mice exposed to cold-water stress	Increased SP; increased IL-6 release by macrophages
	Stressed rats (restraint and sequential removal)	Increased levels of SP in periaqueductal gray area of brain
Human (<i>in vitro</i>)	Bone marrow stroma cells exposed to SP	Increased stem cell factor, IL-1
	Monocytes/macrophages exposed to SP	Increased IL-1, IL-6, IL-7, IL-10, IL-12, TNF- α ; chemotaxis, and phagocytosis
Human (<i>in vivo</i>)	Acute psychological stress in parachutists	Increased SP
	Acute psychological stress in medical diagnostic procedures	Increased SP, CD8 ⁺
	Sickle cell patients in vaso-occlusive crisis	Increased SP correlated with pain; increased IL-8

IL, interleukin; SP, substance P; TNF, tumor necrosis factor.

IL-1, IL-6, and TNF- α . Macrophages in mice exposed to oral salmonella doses expressed higher levels of SP receptors and the administration of the SP antagonist spantide II resulted in higher mortality than in non-SP-antagonized mice. Treatment with spantide II was also associated with significantly reduced levels of IL-12 and IFN- γ . Thus, SP serves to amplify ongoing immune reactions and serves as a mediator in stress-induced immune reactions.

Stress System

Syndromes of Major Depression

Glossary

<i>Amygdala</i>	Brain region involved in the expression and acquisition of conditioned fear.
<i>Atypical depression</i>	Major depressive disorder with a predominance of somatic features (increased appetite, sleep, and weight gain) that are the inverse of what is seen in melancholia.
<i>Cushing's disease</i>	A disorder characterized by the clinical effects of increased circulating glucocorticoids caused by a pituitary ACTH-producing microadenoma.
<i>Major depression</i>	A psychiatric disorder characterized by depressed mood, loss of pleasure in most activities, and symptoms that affect cognitive function, appetite, weight control, sleep patterns, and sexual function.
<i>Melancholia</i>	A historical term that designates the presence of decreased appetite, weight loss, complete lack of pleasure, insomnia, and early morning worsening of symptoms in a patient with major depression.

Stress System

The stress response consists of a simultaneous repertoire of behavioral and physiological adaptations that promote survival during threatening situations. The most apparent are fear-related behaviors that include anxiety, decreased exploration (or freezing), increased vigilance, and intense focus on the threatening stimulus. Concurrently, there is evidence of physiological activation of both the hypothalamic-pituitary-adrenal (HPA) axis and the sympathetic nervous system. Metabolically, a catabolic state ensues that mobilizes fuel for the stressed body site or the brain, and endocrine programs for growth and reproduction are inhibited. Finally, there is systematic inhibition of vegetative functions whose execution would impair the likelihood of survival during a life-threatening crisis (e.g., feeding, sexual behavior, and sleep).

This section focuses on the core stress systems, the corticotropin-releasing hormone (CRH) (including the HPA axis) and the locus ceruleus–norepinephrine (LC–NE) systems. We also discuss the importance of other relevant neural substrates to the stress response and major depression.

Corticotropin-Releasing Hormone

Several discrete CRH systems have been identified in the brain. CRH was first discovered as the hypothalamic hormone that plays the principal role in the regulation of the HPA axis. Intrahypothalamic CRH pathways contribute to the inhibition of feeding and sexual behavior and to the inhibition of endocrine programs for growth. Parvocellular CRH neurons in the paraventricular nucleus (PVN) of the hypothalamus send terminals to brain stem arousal and autonomic centers. An extrahypothalamic CRH system has been identified in the amygdala and is important in modulating aversively charged emotional memory. The administration of a CRH antagonist directly into the central nucleus of the amygdala (CEA) diminishes fear conditioning significantly. These CRH pathways represent the anatomical context for the observation that the intracerebroventricular administration of CRH recapitulates many of the metabolic, endocrine, autonomic, and behavioral features of the stress response. While it is well known that cortisol participates in a classic negative feedback loop to restrain the HPA axis, amygdala and descending hypothalamic CRH pathways are actually activated by cortisol. Cortisol also contributes significantly to the inhibition of programs for growth and reproduction seen during stress, as well as to feedback restraint on an activated immune system ([Figure 1](#)).

Locus Ceruleus–Norepinephrine System

The LC–NE system originates in the mid-pons and sends a dense network of terminals to many cortical and subcortical structures. The LC–NE system serves globally as a generalized warning system, inhibits vegetative functions such as grooming, eating, and sleeping, and contributes to accompanying increases in autonomic outflows. Ascending norepinephrine pathways project to the PVN CRH neurons and exert excitatory effects on the HPA axis. Brain stem norepinephrine, in turn, also influences other key structures that work together with the core stress system components, including the amygdala.

Dotted lines indicate inhibition and solid lines indicate stimulation.

CRH/LC-NE Systems and Interactions with Neural Substrates of Relevance to the Stress Response and Depression

Activation of the stress system sets into motion a range of fear-related behaviors and promotes the encoding of conditioned fear. The amygdala is the key structure involved in conditioned fear, and, as noted, CRH in the central nucleus of the amygdala in the rat plays an important role in this phenomenon. Activation of the amygdala is associated with activation of the HPA axis, most probably via direct projections from the CEA to the PVN. There is also evidence that the amygdala can activate the HPA axis indirectly via projections to brain stem catecholaminergic centers.

The classic effect of glucocorticoids on the CRH system is the negative feedback effect exerted on the HPA axis. Glucocorticoid receptors in the hippocampus play an important role in mediating this negative feedback restraint. However, not all glucocorticoid effects on the CRH system are inhibitory. Thus, glucocorticoids actually enhance the expression of CRH in the CEA and increase fear-related behaviors. This glucocorticoid effect provides the context for a feed-forward loop between the amygdala and the HPA axis.

The core stress systems and the amygdala are also linked closely to the medial prefrontal cortex (MPC). This complex structure is important in promoting the extinction of conditioned fear encoded in the amygdala and, by doing so, exerts restraint on stress system activity. Pathways from the MPC to the brain stem

also inhibit brain stem autonomic centers. This structure also sends the only direct cortical connections to the hypothalamus, and the activation of glucocorticoid receptors located in the MPC inhibits the HPA axis. It has been shown that the chronic hypercortisolism of Cushing's disease is associated with a significant decrease in the size of the prefrontal cortex. This finding suggests the possibility of another feed-forward loop in the context of sustained hypercortisolism, a state in which the inhibitory actions of the MPC on the hypothalamus would be impaired due to cortisol-mediated atrophy.

The medial prefrontal cortex is also involved in a critical array of complex behaviors. This structure helps decide whether a particular situation is likely to result in reward or punishment and is involved in the shifting of affect from one state to another based on internal and external cues and in orchestrating sequences of sophisticated repertoires of motor activity and behavior. Activation of the amygdala takes the medial prefrontal cortex off line, thus inhibiting complex, innovative behaviors and promoting the kinds of autonomic, stereotyped repertoires that would be most adaptive in an immediately life-threatening situation.

Syndromes of Major Depression

Definition

Depression affects up to 15% of women and 8% of men worldwide. According to the World Health

Organization, depression is a greater source of morbidity for women than any other illness. The *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV), edited by the American Psychiatric Association, provides clinicians and researchers with criteria to diagnose someone who suffers from depression. Major depressive disorder, as the condition is named, is characterized by depressed mood or inability to experience pleasure and at least four of the following associated symptoms: feelings of worthlessness, suicidal thoughts, diminished concentration, and changes in weight, appetite, psychomotor activity, and sleep. The symptoms have to be severe enough to cause impairment in the patient's daily activities, and they have to last at least 2 weeks in order for the diagnosis to be firmed. The causes of the disorder are not known. Stressful life events play a role in the course of the disorder, and there are studies demonstrating the importance of heritable factors.

Phenotypic Subtypes of Major Depression

Major depression is a disorder that is clinically heterogeneous. Although the core symptoms (depressed mood and inability to experience pleasure) need to be present, there are many distinct clinical presentations of the disorder. Differences in the subtypes of major depression are determined by the combination of the associated features. Two subtypes of major depression, namely, major depression with melancholic features (melancholia) and major depression with atypical features (atypical depression), have received the greatest attention from investigators (Table 1).

Although the term depression implies a suppression of thought and feeling, melancholia is instead a state of hyperarousal and fear often stemming from a profound sense of personal unworthiness and pessimism about future prospects. Any loss in cognitive and emotional range is counterbalanced by the intensity of this anxiety, which coincides with, and is perhaps inseparable from, a loss of pleasure in everyday activities. Patients with severe melancholia seem to be in especially close contact with painfully charged memories of past losses and failures. The emotional intensity of melancholia is matched by indices of physiological hyperarousal (insomnia, early morning awakening, and hypercortisolemia). Patients also experience inhibition of vegetative functions: loss of appetite and libido, inhibition of growth, and sex steroid secretion.

In contrast to melancholia, patients with atypical depression often feel much less alive than usual and experience a profound inertia and fatigue that often isolates them and interferes with normal functioning. Characteristically, they sleep excessively, eat a lot,

Table 1 Characteristics of major depression with melancholic features (melancholia) and atypical features (atypical depression)

Characteristic	Melancholia	Atypical depression
Vegetative functions	Insomnia, anorexia, weight loss, diminished libido	Hypersomnia, increased appetite, weight gain
Behavior	Anxious, preoccupied with concerns about deficient self, preferential access to dysphorically charged memories	Partial reaction to positive stimuli, intense fatigue, diminished sense of connection to self
Stress system Medical consequences	Hyperactive Osteoporosis, increased cardiovascular morbidity and mortality, prefrontal cortex abnormalities	Hypoactive Autoimmune disorders?
Response to treatment	Similar response to different classes of antidepressants	Preferentially to MAOIs ^a

^aMonoamine oxidase inhibitors, an antidepressant medication that acts on the catabolic path of monoamines.

and usually gain weight. Like patients with melancholia, they have a diminished libido and a blunted capacity to experience everyday pleasure, although they may react temporarily to positive external and internal clues (mood reactivity).

Major Depression as a Disorder of Adaptation

As reviewed previously, the stress response system is a stereotyped, adaptive repertoire that ensures survival during threatened homeostasis. Major depression, by definition, is associated with relatively unshifting affect and simultaneous changes in fundamental biological processes that regulate sleep, food intake, metabolism, and reproduction. Similarities between the stress response and the phenomenology of melancholia prompted us to first postulate that the clinical and biochemical manifestations of this disorder reflect a dysregulation in stress system mediators. Changes seen during the stress response are under strict control by counterregulatory mechanisms that serve to limit the response in time and magnitude. Melancholia can be seen as a state of chronically and excessively activated stress response, possibly due to an escape of the usual regulatory influences. In that sense, melancholia would be a disorder of adaptation, more specifically, one in which the stress response required for survival becomes dysregulated and is the very source of the

illness. In contrast, many symptoms found in atypical depression can reflect a pathological inactivation of stress system mediators. The remainder of this article reviews the lines of evidence indicating the convergence between a dysregulation of the stress response and the biochemical and neurobiological findings in both subtypes of major depression.

Major Depression with Melancholic Features

Hypercortisolemia and hypothalamic CRH secretion

Sustained hypercortisolism has been demonstrated repeatedly in patients with major depression and is perhaps the best documented finding in the biology of psychiatric disorders. Many lines of evidence indicate that hypercortisolism of major depression is due to the hypersecretion of hypothalamic CRH neurons. Data obtained in brains taken from patients who had suffered with affective illness reveal overexpression of CRH in the hypothalamus.

Norepinephrine secretion Patients with melancholic depression show sustained and profoundly elevated levels of cerebrospinal fluid (CSF) NE when sampled through an indwelling lumbar drain for 30 h. Moreover, CSF NE levels were highly elevated during sleep, indicating that the hypersecretion of centrally directed norepinephrine was not an artifact of the conscious distress of the illness. Increased basal norepinephrine spillover into arterialized venous blood was noted in patients with major depression with melancholic features. We have subsequently replicated this finding in arterial plasma and have shown that patients with melancholic depression show significantly higher norepinephrine spillover than controls in response to psychological and pharmacological stimuli. Our patients also showed significantly higher basal heart rates and heart rate increases to psychological and pharmacological stressors.

Pathophysiology of melancholic depression The reciprocal connectivity of the structures that participate in the modulation of the core stress system suggests that similar phenotypes can be generated by primary defects in any of these structures, including the prefrontal cortex, the amygdala, or the CRH/LC-NE systems. For example, data showed a decrease in the volume and metabolic activity of the left subgenual prefrontal cortex in patients with major depression. Theoretically, an initial decrease in the function of the MPC could potentially enhance amygdala activation as well as the activation of the HPA axis and brain stem noradrenergic neurons. An activated amygdala and hypothalamic CRH centers would further activate brain stem arousal and autonomic centers.

An increased noradrenergic drive from the brain stem could potentiate the activity of the HPA axis. Hypercortisolism in major depression could be enhanced further by the capacity of glucocorticoids to damage or destroy hippocampal glucocorticoid receptor-containing neurons that mediate negative feedback on the HPA axis. In this regard, Sheline and colleagues found that patients with depressive episodes in the past had diminished bilateral hippocampal volumes compared to controls matched by age and medical conditions.

Taken together, a number of feed-forward loops among key components of the stress system could emerge that would intensify the stress system dysfunction in major depression, leading to a diminished activity of the medial prefrontal cortex and activation of the amygdala, HPA axis, and brain stem noradrenergic centers. The final result could be a syndrome associated with a relatively stereotyped affect, increased fear, and activation of the HPA axis and sympathetic nervous system. Such a syndrome would closely resemble the syndrome of melancholic depression.

Long-term medical consequences Patients with major depression exhibit a number of neuroendocrine and autonomic changes that could potentially predispose them to long-term medical consequences such as osteoporosis and premature ischemic heart disease. Hypercortisolism and suppression of the growth hormone and reproductive axes during depressive episodes would be expected to result in loss of bone mineral density. Unfortunately, bone mineral density, once lost, is not regained easily. In a study of premenopausal women (average age 41) with past or current major depression, almost 40% showed a loss of bone mineral density at the hip or spine that was at least 2 standard deviations below peak bone age, thus meeting American Osteoporosis Society criteria for osteoporosis. Because peak bone age is reached at around age 30, this means that these patients had lost more than an average of 1.5% of bone mineral density per year. Thus, by the time they enter menopause, these patients could have severe osteoporosis with losses as great as 35% below peak bone mass. Because each 10% decrease in bone mineral density is associated with a doubling of the fracture rate, the bone loss seen associated with depression represents an additional risk to fractures in aging women.

Patients with major depression show an overall increase in mortality regardless of age (independent of suicide). This relates, in part, to the fact that the relative risk for ischemic heart disease in patients with major depression is two or more and this increased risk is independent of traditional risk factors such

as hypertension, dyslipidemia, and smoking. Many of the changes noted in depression could contribute to this enhanced susceptibility, including hypercortisolism and inhibition of the growth hormone and reproductive axes (leading to, among other things, increased visceral fat mass), with the resultant insulin resistance and its sequelae. Norepinephrine and epinephrine spillover studies showed that patients with depression had higher basal and stimulated heart rates and elevated norepinephrine spillover rates in the context of normal epinephrine secretion. These data strongly suggest increased cardiac sympathoneural activity in patients with major depression, another likely risk factor for ischemic heart disease. Thus, major depression with melancholic features is not only a disorder that affects fundamental parameters that define our humanity, such as self-regard, but also the product of sustained dysregulation in global neuroendocrine and autonomic functions acting on the myriad of peripheral substrates subjected to their influences.

Major Depression with Atypical Features

Biochemical manifestations and pathophysiology Relatively few studies have been conducted on the neurobiology of atypical depression; most have focused on HPA axis regulation. We studied patients with Cushing's disease, a rare illness characterized by severe hypercortisolism and a high incidence of depression. We demonstrated that depression in those patients was almost all of the atypical subtype. After having shown that the profound hypercortisolism of Cushing's disease was attributable entirely to a pituitary rather than central defect, we then focused on the function of hypothalamic CRH-containing neurons in Cushing's disease. In a series of studies, we showed that hypothalamic CRH-containing neurons in patients with Cushing's disease were suppressed by long-standing hypercortisolism. This confluence of atypical depression with a suppressed CRH system led us to hypothesize that some forms of atypical depression were associated with a pathological suppression rather than activation of arousal producing stress mediators.

In subsequent studies, we determined the pattern of plasma ACTH and cortisol responses to ovine CRH in patients with known hypothalamic CRH deficiency, secondary either to traumatic pituitary stalk section or to hypothalamic neoplasia. These patients often showed blunted and delayed plasma ACTH and cortisol responses, indicating that the adrenal cortex had been hypostimulated in these subjects. To test the hypothesis that patients with fatigue states and classic forms of atypical depression might show evidence of

hypothalamic CRH deficiency, patients with seasonal affective disorder and patients with chronic fatigue syndrome were studied. Seasonal affective disorder is characterized by the classical phenotype of atypical major depression. Both of these groups showed plasma ACTH and cortisol responses to CRH similar to those seen in patients with hypothalamic CRH deficiency. We have also shown this pattern in patients with atypical depression studied in the postpartum period.

In summary, these observations raise the question that the presentation of atypical symptoms (lethargy, fatigue, hypersomnia, and hyperphagia), as seen in Cushing's disease and in atypical depression, might be associated with hyposecretion of hypothalamic CRH. More studies will be needed to definitively document this important point.

Potential medical implications of HPA axis dysfunction in atypical depression If a centrally mediated hypoactivity of the HPA axis were documented in patients with atypical depression, this finding could have implications both for the clinical features of atypical depression, such as lethargy, fatigue, and hyperphagia, and for susceptibility to long-term medical consequences. Data show that peripheral inflammatory mediators such as interleukin-6 and tumor necrosis factor activate hypothalamic CRH neurons and the hypothalamic-pituitary axis. This circuit, during inflammatory stress, has been shown to promote HPA activation and glucocorticoid-mediated restraint of the immune response. The putative role of hypothalamic CRH and subsequent pituitary-adrenal activation is as a counterregulatory restraint on the immune response. Thus, it has been postulated that during the stress of a fight-or-flight situation, inflammatory mediators recruit the HPA axis to prevent the immune response from overshooting in the context of an anticipated injury and powerful inflammatory stimulus.

In *in vivo* studies, we and others have shown that adrenalectomized rats given an inflammatory stimulus show a profoundly exaggerated inflammatory response that, in some instances, resulted in death. In addition, we have shown that susceptibility to inflammatory disease in Lewis rats is associated with the hypoactivity of hypothalamic CRH in response to inflammatory mediators and other stimuli. Lewis rats also show significant attenuations in behavioral and other physiological responses to inflammatory mediators and other stressors. In the light of these data, we propose that patients with atypical depression could represent the tip of the iceberg of subjects who complain of lethargy, fatigue, and apathy, as well as an array of low-level but persistent complaints

such as muscle pain, joint pain, and allergic phenomena. We are currently continuing to test this hypothesis utilizing new paradigms that will hopefully provide sufficient resolution to detect subtle hypoactivity of the HPA axis secondary to a change in CRH function.

Glossary

Physical abuse Physical violence directed toward an intimate partner including pushing, slapping, punching, kicking, choking, assault with a weapon, tying down, and restraining;

Psychological abuse

Sexual assault

threats of bodily harm and threats of violence directed at the woman's children; and behaviors liable to cause fear of physical safety such as leaving a woman in a dangerous place, driving fast and recklessly to frighten her, and refusing to help when she is sick or injured.

Abusive behaviors whose damage is primarily emotional including physical and social isolation, extreme jealousy, possessiveness, and removing access to communication or transportation; deprivation, degradation, and humiliation; emotional distress inflicted through threats to harm companion animals or livestock; and intimidation, intense criticizing, insulting, belittling, and ridiculing.

Forced sexual acts or sexual degradation, such as coercing a woman to perform sexual acts against her will; hurting her during sex or assaulting her genitals, including using objects intravaginally, orally, or anally; pursuing sex when she is not fully conscious or otherwise un-

Stalking

able to consent; insisting on sex without protection against pregnancy or sexually transmitted diseases; and forcing her to have sex with others either privately or while being observed by the partner; often part of violent relationships.

A pattern of repeated harassing or threatening behavior including following a woman, appearing at her home or place of business, making harassing phone calls, leaving written messages or objects, and vandalizing her property, even in the absence of threat of serious harm.

Male partner violence is broadly defined to be inclusive of the various types of behaviors that are used to coerce, control, and demean women. According to a report on intimate partner violence by the U.S. Department of Justice, 20% of all nonfatal violence against women in 2001 was committed by current or former spouses or boyfriends, whereas intimate partners committed 3% of nonfatal violence against men. Women are at a greater risk of assault, including rape and homicide, by a husband, ex-husband, boyfriend, or ex-boyfriend than they are by an acquaintance or stranger. Some methodologies generate data showing equal rates of intimate partner violence by men and by women; however, women are more likely to sustain minor or serious injuries. Violence within an abusive relationship is characterized as a recurrent experience when a woman is repeatedly placed in physical danger or controlled by the threat or use of force. Specifically included in these definitions, along with physical assault, are sexual assault, battering, threats, intimidation designed to obtain power and control by inducing fear in the victim, and stalking. The United Nations, the American Medical Association, and the American Psychological Association Presidential Task Force on Violence and the Family have established definitions of violence that recognize a pattern of physical, sexual, and/or psychological acts aimed at harming, intimidating, or coercing someone who is or was involved in an intimate relationship with the perpetrator.

Prevalence

Over the past 25 years, researchers have documented that violence by male intimates is one of the most prevalent and serious threats to the well-being of women in the United States and internationally. The landmark 1998 National Violence Against Women survey (NVAW), consisting of telephone interviews with 16,000 men and women, found that 25% of the women surveyed had been raped and/or physically assaulted in their lifetime by a current or former

spouse, cohabiting partner, or date. The National Crime Victimization Survey (NCVS), an annual general survey of crime, indicated that the rate of intimate partner violence against women dropped by 49% between 1993 and 2001 but that the rate in 2001 was still high. There was an estimated 691,710 nonfatal incidents of violence committed by current or former spouses, boyfriends, or girlfriends, and the victims were primarily women (85%). These estimates, however, must be understood in the context of the limitations of the methods used to obtain them. National estimates based on telephone surveys are likely to be conservative due to the exclusion of the homeless, those too poor to own a telephone, people with limited English, recent immigrants who may be fearful of the government, and women whose partners control their ability to freely receive calls. Household-based samples mean that several living situations are missed in which women may be at high risk for violence including prisons, psychiatric hospitals, military settings, and colleges. These and other differences in methods contribute to substantial variation in estimate size across surveys.

Physical Assault

The NVAW documented that 22% of women were physically assaulted by current or former intimate partners during their lifetime. The majority of assaults were relatively minor, involving pushing, grabbing, and shoving. Few incidents involved more extreme forms of aggression, such as kicking or beating, threatening with a knife or gun, or using a weapon.

Sexual Assault

NVAW have shown that more than 7% of women report being raped by a current or former intimate partner in their lifetime. Those subjected to physical abuse are especially vulnerable to sexual abuse, with 26% to 52% of physically abused women reporting also being raped. Men who are both physically and sexually abusive are consistently found to perpetrate the most violent and severe assaults on their partners, with the majority of victims being repeatedly assaulted during the course of the relationship. Women who are victims of both physical and sexual violence are also at greater risk for abuse during pregnancy as well as at greater risk of homicide.

Psychological Abuse

Emotional abuse is generally concomitant with physical or sexual assault. In a recent study of primary-care patients, all women who were physically abused also reported emotional abuse in that relationship. The Canadian Centre for Justice Statistics National

Survey on Violence Against Women included questions on jealousy, limiting contact with family or friends, belittling and insulting female partners, preventing access to family income, and insisting on knowing a partner's whereabouts at all times. Approximately one-third of ever-married women in Canada reported that their current or previous partner was emotionally abusive in at least one of these five ways. In the majority of cases, emotional abuse was concomitant with physical or sexual abuse; only 18% of women who experienced emotional abuse reported no physical violence by a partner.

Stalking

Stalking by male partners also threatens the health of women. Based on a definition that includes experiencing fear, approximately 5% of women (compared to about 1% of men) have been stalked by a current or former intimate partner in their lifetime, according to the NVAW. Among women who were stalked by a former or current partner, 81% were also physically assaulted and 31% were sexually assaulted by the same man. Stalking frequently escalates among women who have left their abusive partners. The likelihood of being stalked by a male partner increases with the duration of time that the woman has been separated from the abusive relationship.

Risk Factors

Various factors increase the likelihood that a woman will be assaulted by a male partner. Research has identified several demographic risk factors. They include being younger in age; being single, divorced, or separated; having lower income; and having less education. In addition, ethnic minorities report higher rates of male partner violence compared to Whites. The NVAW indicated that American Indians/Alaska Native women had the highest rates, followed by African Americans. White and Hispanic women reported similar rates and Asian/Pacific Islanders reported the lowest rates of victimization by an intimate partner. These differences may reflect, in part, socioeconomic differences. However, researchers have found that differences in risk exist even after controlling for such variables. It is of note that studies consisting of only Native American samples have shown that some tribes have higher rates of partner violence, whereas others do not. Immigrant women experiencing partner violence are also a vulnerable population because they are often isolated in a foreign country, in constant fear of deportation, and feel at the mercy of their spouse to gain legal status. A history of childhood physical abuse, alcohol-related problems, drug use, and certain personality characteristics also increase the likelihood that women will be assaulted

by a male partner. Certain characteristics of the male partner also increase the risk of victimization, including childhood exposure to intimate partner violence, partner alcohol-related problems, and emotionally abusive and controlling behaviors.

Psychological Impact

Victims of male partner violence are subject to physical, emotional, and perhaps sexual violence over an extended period of time. The impact on a woman's mental health is thus not derived solely from specific acts of violence but rather from the stress of living with recurrent, escalating, and unpredictable attacks. Not surprisingly, the severity and frequency of violence is associated with an increase in mental health symptoms, and symptoms have been shown to decrease when a woman is free from the abuse.

Posttraumatic Stress Disorder

Posttraumatic stress disorder (PTSD), as defined in the Diagnostic and Statistical Manual of Mental Disorders, fourth edition, has become the predominant diagnosis used to describe the various symptoms of psychological trauma exhibited by partner violence victims, with intensity of exposure being the primary etiological variable for PTSD. Rates of PTSD among abused women range from 31 to 84%. The occurrence of sexual assault in marriage is associated with greater trauma, more severe depression, and lower self-esteem than is found among victims of physical abuse alone. The most common symptoms of the disorder among abused women are nightmares, intrusive memories of abuse, avoidance of reminders of the abuse, and anxiety symptoms. Victims may also exhibit cognitive symptoms such as difficulty concentrating, problems with memory, and anger.

There is concern within the mental health profession and among victim advocates regarding the constructive use of PTSD as a diagnostic tool. PTSD pathologizes the victim's response to violence rather than focus the source of the trauma. In treating the symptoms of PTSD, the causal role of violence is neglected, placing victims at risk of misdiagnosis, inappropriate medication, and even possible further abuse. In addition, the victim may perceive the diagnosis as evidence of her own inadequacy rather than as condemnation of the violent behavior being perpetrated on her. Research has shown that access to both social support and victim advocacy services leads to a reduction in PTSD symptoms among abused women.

Depression

Prior to the introduction of PTSD, depression was the preferred diagnosis for victims of partner violence.

Today, depression continues to be prevalent among victims of intimate partner violence with rates varying between 39 and 83%. Women are more likely to be diagnosed with either depression or PTSD, and an investigation of the co-occurrence in physically abused women found that only 17% met the criteria of both. Depression is more likely among victims when psychological and sexual abuse occur within a physically violent relationship. Having low levels of social support has also been associated with depressive symptoms among victims.

Although it is imperative to investigate, document, and respond to the impact of trauma on the mental health of victims, the attempt to diagnose a woman trapped in a violent relationship with a mental disorder may be counterproductive.

Other Psychiatric Disorders

Victims of male partner violence are at greater risk of alcohol abuse and illicit drug use than nonabused women. Although partner violence may involve alcohol consumption by the female victim, or by the perpetrator and victim, increased alcohol use and illicit drug use by women frequently follows victimization. Compared to nonvictims, victims are also at higher risk for exhibiting eating disorders and more likely to report attempted suicide.

Physical Impact

Researchers and health-care providers worldwide single out partner violence as a major public health threat to women. The most severe physical outcome is death. Approximately 30% of murders of women that occurred between 1976 and 1996 were committed by male partners. The majority of these women were abused by a partner prior to being killed. Female victims also experience high rates of short-term and long-term health consequences. Children are also often affected because of prenatal or postnatal exposure to violence. Therefore, it is not surprising that women with a history of partner abuse demonstrate increased health-care use. Female victims of partner violence seek care for violence-related injuries, general health problems, and mental health problems.

Acute Injuries

Male partner violence is the largest single cause of injury to women requiring emergency medical treatment. Estimates of emergency department visits by women due to partner assault are between 13 and 25%. In a Bureau of Justice Statistics report on violence-related injuries treated in hospital emergency departments, only 14% of the injuries treated in

women were inflicted by strangers compared to 29% in men. Physically abused women experience injuries to multiple parts of the body, including injuries to the face, head, neck, throat, breast, chest, and abdomen. Battered women are more likely to have abrasions and contusions or pains for which no physiological cause can be discovered. Fractures, dislocations, and lacerations occur with about equal frequency in abused and nonabused women. One of the most troublesome aspects of male partner violence is the recurrent and often escalating nature of the abuse. Women who frequently present for medical treatment of trauma are likely to have been treated previously for injuries from abuse. Victims of partner violence have on average seven treatment episodes in the emergency service compared to two among nonbattered women. The pattern of escalation is also evident in homicide rates. In one study, 14% of the women who were killed had been in the health-care system for violence-related injuries. Approximately 47% had received health-care services for some type of problem during the year before they were killed.

Chronic Health Problems

Women of all ages with a history of past or current partner abuse are disproportionately represented among women receiving a variety of services in primary-care settings. The injuries, emotional stress, and fear associated with male partner violence can contribute to the development of chronic health problems. They include chronic pain (e.g., headaches and back pain) and central nervous system symptoms, such as fainting and seizures. Women who have been abused report higher rates of gastrointestinal symptoms and functional gastrointestinal disorders, such as irritable bowel syndrome and nonulcer dyspepsia, compared to other women. These disorders have no known pathogenesis or established treatment and are the most common chronic gastrointestinal conditions seen in primary care, as well as the most common reason for referral to gastroenterologists. In various clinical samples, between 44 and 67% of all female gastroenterology patients report a history of sexual violation, and between 32 and 48% of female patients had experienced severe physical trauma in childhood or adulthood. Gynecological problems are also long-lasting outcomes of male partner violence. Symptoms and conditions include HIV infection, other sexually-transmitted diseases, vaginal bleeding or infections, decreased sexual desire, genital irritation, painful intercourse, chronic pelvic pain, and urinary tract infections. The likelihood of having a gynecological problem is three times greater among women who are abused by spouses.

Birth Outcomes

Because young women in their most active childbearing years are at highest risk for abuse, abuse during pregnancy deserves special mention. Women who are abused and pregnant are more likely to engage in poor maternal health behavior. They frequently delay prenatal care. Compared to nonabused women, women who are abused are twice as likely to delay prenatal care until the third trimester. Pregnant women who are abused report higher levels of alcohol, tobacco, and drug use than other pregnant women. Pregnancy complications may include preterm labor, low birth weight, spontaneous abortion, anemia, and infections. It is also important to mention the effects of intimate partner violence on children. Children who observe violence against their mothers are at higher risk of emotional, behavioral, physiological, cognitive, and social problems.

Prevention

Primary Prevention

The aim of primary prevention, as applied in public health, is the reduction of the risk of obtaining a disease or health condition. Specific to male partner violence, primary prevention focuses on learning not to use violence. Primary prevention strategies include changing social norms promoting violence against women, changing male roles, promoting the status of women, and increasing the public's awareness of the problem of male partner violence. Other approaches focus on training to improve relationship, conflict resolution, and anger management skills.

Secondary Prevention

Secondary prevention occurs when an individual has a disease or health condition, but health consequences have not yet developed. One approach for partner violence is to conduct violence screening in health-care settings and non-health-care settings, such as workplaces, schools, and military bases. Intimate partner violence screening facilitates early identification and treatment referrals for female victims. Specific to perpetrators, secondary prevention efforts include training to deescalate aggression and counseling and hotlines for violent partners.

Intervention

The response to male partner violence must include effective interventions, not only in specific cases of victimization but in communities and from a societal perspective. Beyond providing victim services, communities need to develop a coordinated response

across different types of agencies, and public policy needs to counter the systemic issues related to male partner violence.

Mental Health Services

Mental health clinicians have the potential to play a vital role in assisting the recovery process for survivors of partner violence. However, to avoid retraumatizing the survivors, clinical services must focus on providing specific interventions to counter the impact of trauma rather than on the mental disorders of the victim. For a woman living in a violent situation, mental health practitioners should prioritize her physical safety and assisting her to access victim services as a first step in addressing mental health concerns. Key to this process is assisting women to identify and develop formal and informal support networks that will help facilitate situational realities associated with both living in or leaving a violent relationship. For this to be feasible, strong linkages need to be fostered between clinical services and women's services, such as advocacy centers, domestic violence shelters, and rape crisis organizations. Additional resources are also needed to ensure that women who are using victim services, for example, those living in shelters, are able to access appropriate clinical services.

Coordinated Community Response

Mental health services should also be addressed within the framework of implementing a coordinated community response to partner violence. The development of coordinated community response is an outgrowth of the efforts of women's advocates to make reforms within the often-fragmented criminal justice system. The objective of the coordinated community response is to ensure that components of the system work together to form a consistent and systematic response that shifts responsibility away from victims and holds perpetrators of violence responsible for their behavior. Women's safety is considered of primary importance. Within this framework, emphasis is placed on batterer rehabilitation programs and support and advocacy for victims, but not specifically on the provision of clinical services for women suffering from trauma. Accessibility to immediate, appropriate clinical services could serve to avert the escalation of trauma symptoms.

Public Policy and Advocacy

Examples of proactive public policy are demonstrated in the Violence Against Women Act (VAWA) of 1994, which sponsored legislation to support increased police personnel, higher levels of prosecution, more

severe penalties for perpetrators, and extended victim services. VAWA also recognized that immigration law placed abused women at risk and provided relief by giving abused immigrant women the means to establish lawful permanent residence without the help of a spouse. VAWA 2000 strengthened protections for battered immigrant women, sexual assault survivors, and victims of dating violence. Appropriate interpretation and enforcement of mandatory arrest laws is another area of public-policy intervention that should be pursued. Coupled with an advocacy agenda is the need for a public health response. This perspective, emphasizing the establishment of screening protocol, early interventions, and multiple approaches to prevention, offers hope of reducing the incidence of partner violence and minimizing its effects.

Conclusion

Women's Advocates Incorporated calculated in 2002 that intimate partner violence costs the U.S. economy \$12.6 billion on an annual basis in legal services, direct medical care, policing, lost productivity, and victim services. Efforts have been made in the past decade to address this issue through initiatives such as mandatory arrest and sentencing laws within the criminal justice system and the development and implementation of screening protocols by health and social service organizations. However, the fact that thousands of women are injured or killed each year by an intimate partner indicates the need for social norms to be addressed. There is much to be done in terms of creating a comprehensive systematic response to male partner violence both in the United States and internationally, and the lack of such response contributes to the perception of societal support or even encouragement of violence. Although victims and perpetrators must both have access to appropriate intervention, the prevention of male partner violence is of paramount importance and requires action on a multiple levels.

What Are the Consequences of Conflict?

Glossary

Demand–withdraw interaction

A pattern of interaction in which one member of a couple attempts to engage in the discussion of relationship issues and pressures, nags, demands, or criticizes the other while the other member attempts to avoid such discussions and becomes silent, withdraws, or acts defensively.

Process of conflict

The interaction that takes place around a conflict of interest.

Psychoneuro-immunology

The study of the interactions among the psychological, neurological, and immunological systems.

Structure of conflict

The conflict of interest between spouses; the incompatibility of needs, desires, or preferences that characterize a couple's struggle.

What Is Conflict?

Conflict in marital relationships is normal and inevitable. Indeed, conflict occurs to a much greater extent in marriage than in any other long-term relationship. Although some theorists have suggested that conflict may serve constructive or functional purposes, such as allowing for the disclosure of feelings and the creative resolution of problems, the focus in the marital literature has generally been on the destructive or dysfunctional consequences of conflict.

An important distinction is made in the marital literature between the structure of conflict and the process of conflict. The structure of conflict refers to the conflict of interest between the spouses, that is, the incompatibility of needs, desires, or preferences that characterize the couple's struggle. The process of conflict refers to the actual interaction that occurs between the spouses regarding the conflict of interest.

It is important to note that a particular conflict of interest may give rise to a variety of conflictual processes. Couples may engage in overt conflict about the issue, or they may choose to avoid discussion about the issue altogether. Some theorists suggest that the decision to engage or to avoid is determined by spouses' beliefs about the likelihood that their efforts at resolving the conflict will be successful. Others have suggested that factors such as commitment to the relationship and negative feelings about the partner may also influence engagement or avoidance in conflict.

What Happens During Conflict?

Assuming that the management of conflict affects the quality and stability of the relationship, marital researchers have focused more of their attention on the process of conflict than on the structure of conflict. Researchers often study marital conflict by having couples discuss a conflict of interest in a laboratory setting for a predetermined amount of time (typically 10–15 min) while the resulting interaction is audiotaped or videotaped. Trained observers then code the problem-solving interaction for categories or dimensions of interest. Although the same type of discussion leads to more intense negative affect at home than it does in the laboratory, the observational research paradigm described does produce interactions that are similar to those experienced by couples in naturalistic settings.

One of the objectives of marital research has been to identify conflict behaviors that are associated with relationship satisfaction and thus differentiate between distressed and nondistressed couples. Although a number of differences have been identified, there are a few consistent findings across studies. First, distressed couples display higher rates of negative behaviors during conflictual interactions than nondistressed couples. These negative behaviors include criticism, complaints, hostility, defensiveness, denial of responsibility, and withdrawal. Second, compared to nondistressed spouses, distressed spouses exhibit greater reciprocity of negative behavior. That is, when a distressed spouse behaves in a negative manner, the other spouse tends to respond in kind, which escalates the conflict and leads to a cycle of negativity that is difficult to break. Third, nondistressed couples display higher rates of positive behaviors, such as approval and humor, during conflictual interactions than distressed couples. Similar to this cross-sectional

research, longitudinal research has also demonstrated the deleterious effect of negative interactions on future satisfaction and stability.

A pattern of conflictual interaction that has received much empirical attention and has been found to be highly correlated with marital dissatisfaction is the demand–withdraw interaction pattern. In this pattern, one spouse (the demander) attempts to engage in the discussion of relationship issues and pressures, nags, demands, or criticizes the other while the other spouse (the withdrawer) attempts to avoid such discussions and becomes silent, withdraws, or acts defensively. Although both self-report and observational studies have demonstrated a gender linkage in roles in this pattern, with wives generally in the role of demander and husbands generally in the role of withdrawer, this gender effect is moderated by the specific issue that is being discussed. Specifically, the gender linkage in roles is apparent during discussions in which wives' issues are being addressed, but this linkage is not apparent during discussions in which husbands' issues are being addressed. Also, the pattern often occurs when a structural conflict of interest exists between partners whereby the partners have a differential investment in change on an issue. The spouse who desires a change that can only be achieved through the cooperation of the other (e.g., spending more time together) will generally take on a demanding role during discussion, whereas the spouse who seeks no change or change that can be achieved unilaterally (e.g., spending less time together) will generally take on the withdrawing role because discussion will only create an argument or undesired change.

In addition to studying overt behavior, marital researchers have also examined covert factors that may impact marital conflict and satisfaction, such as affective processes and perceptual differences between spouses. One area that has received much attention in the marital literature concerns the attributions that spouses make in accounting for events that occur in marriage. There is accumulating evidence indicating that attributions for negative events can promote conflict, such as when negative partner behavior is attributed to the selfish intent of the partner. Such attributions have been found to be related to less effective problem-solving behavior and to higher rates of negative behavior during problem-solving tasks. Moreover, research has demonstrated that attributions for negative partner behavior affect a spouse's own behavior toward the partner.

Recent years have seen a growing emphasis on the application of social psychological theories to the study of marital conflict. Attachment theory is one such theory that has been the focus of increased attention in marital conflict research. Attachment

theory asserts that mental models of the self and other develop in the context of early parent–child interactions and that these models influence the communications and reactions of spouses to partner behaviors. Research findings generally suggest that spouses with secure attachment styles are more likely to compromise when dealing with conflict, whereas those with insecure attachment styles tend to employ less productive approaches to marital conflict.

What Are the Consequences of Conflict?

Conflict not only has an effect on the marital relationship itself, but it can also affect the health of individual partners. A growing body of research documents the association between marital conflict and the physical and mental well-being of spouses. Although married people tend to be healthier than those who are not married, marital conflict has been linked to an increase in physical illnesses such as rheumatoid arthritis and cardiac problems. Marital conflict also increases the risk for mental disorders. The association between marital conflict and depression is well established, as is the association between marital conflict and the physical and psychological abuse of spouses. Some of the most compelling data relating marital conflict to mental disorders are seen in the strong linkage between marital conflict and substance abuse.

The link between marital discord and poorer health outcomes has been systematically explored over the past decade. Negative and hostile behaviors during marital conflict are associated with various physiological effects in spouses, such as elevations in blood pressure and heart rate and changes in endocrine and immune functioning. Across studies, these negative physiological effects are more severe and persistent for wives than for husbands. Research in the field of psychoneuroimmunology suggests that there are negative long-term health consequences for spouses who are unable to physiologically recover from marital conflicts or cannot adapt physiologically to repeated conflicts.

In addition to its negative effects on spouses, marital conflict is related to problems in family functioning, including parenting and sibling relationships. Moreover, research has demonstrated the effects of marital conflict on the parent–child relationship, such as attachment difficulties and parent–child conflict, and to a wide range of adjustment problems in children, including internalizing problems such as depression and anxiety and externalizing problems such as aggression, delinquency, and conduct disorders. Exposure to frequent and severe marital conflict, such as physical aggression, seems to be particularly disturbing for children.

Not only is marital conflict itself a stressor, but other life stressors can affect marital conflict. For example, greater work demands among air traffic controllers and unemployment in blue-collar workers have been shown to be associated with more negative marital interactions. Stressful events may increase conflict by diminishing the capacity of spouses to provide support to one another, even as it increases their need for support. Such events may also affect marital interactions by giving rise to new conflicts of interest or by exacerbating old ones.

Glossary

<i>Determinants of health</i>	Factors associated with health and illness, such as socioeconomic status and alcohol consumption.
<i>Intermediary factors</i>	Determinants of health through which marital status affects health outcomes.
<i>Unmarried</i>	People who have never been married, are divorced, or are widowed.
<i>Selection</i>	The theory about health differences between marital status groups in which it is assumed that health affects marital status.
<i>Social causation</i>	The theory about health differences between marital status groups in which it is assumed that marital status affects health.

Marital status is associated with all kinds of health outcomes: both subjective health states (illness, e.g., self-perceived health) and objective health states (disease, e.g., clinically diagnosed conditions), both mental and physical health, and both morbidity and mortality. Health differences between marital status groups are generally assumed to result from both an effect of health on marital status (selection) and an effect of marital status on health (social causation). Marital status affects health through several intermediary factors; of these, psychosocial factors, especially psychosocial stress, occupy a central position.

Health Differences among Marital Status Groups

The general pattern for health differences among marital status groups is that married people have the fewest health problems, followed by never-married and widowed people, whereas divorced people have the most health problems. This ranking is found both among men and women; however, the differences among the marital status groups are generally larger among men than among women.

In most studies in which separated people are distinguished as a separate group, it is found that they have as many as or even more health problems than divorced people. However, in many studies on health differences among marital status groups, separated people have not been treated as a separate marital status category but have been grouped with either divorced or married people.

In many Western countries, nonmarital cohabitation is of increasing importance. The few studies that have addressed health differences between married people and people living in consensual unions have found either no health differences or that the health of people in consensual unions compared somewhat unfavorably with that of married people but favorably with that of the unmarried, noncohabitating people. The remainder of this article focuses on health differences among married, never-married, divorced, and widowed people.

Mortality

Mortality differences among marital status groups were described in the nineteenth century. For instance, in 1853 William Farr examined age-specific mortality rates for never-married, married, and widowed people living in France. He found that the mortality rates of married men and women compared favorably to those of never-married and widowed men and women. For example, at the ages 40–50 mortality rates were 17.7, 10.3, and 20.1 per 1000 for never-married, married, and widowed men, respectively.

Since then numerous researchers in many countries have looked at mortality differences among marital status groups. A considerable number of studies have been performed on this subject in the last decades. The results from these studies indicate very consistently that married people have lower mortality rates than unmarried people.

The sizes of the mortality differences between married and unmarried groups and the rankings of the mortality rates of the three unmarried groups have changed over time. For instance, in the Netherlands in the period of 1869–1872, the differences in total mortality between married and never-married women were rather small, and under the age of 40 never-married women actually had lower mortality rates than married women. This was mainly due to the high childbirth mortality rate among married women. In the following decades, the differences in total mortality between married and never-married women increased as, childbirth mortality rate, among others, decreased.

The relationship between marital status and mortality also shows some differences between countries. Hu and Goldman explored mortality differences between marital status groups in 16 industrialized countries for the period of 1950–1980. They found that, for the majority of countries, divorced men experienced the highest mortality rates among men and that, in about half of the countries, the same pattern existed for women. Generally, the mortality rates of divorced men and women were 2–2.5 and 1.5–2 times, respectively, those of their married counterparts. In Japan, however, the mortality rate of never-married men was as high as the rate of divorced men and never-married women had much higher mortality rates than divorced women. Also, mortality rate differences between the never-married and married in Japan far exceeded the largest mortality rate differences by marital status in the other countries (being more than three times that of the married group).

The differences in total mortality rates among marital status groups are more or less mirrored in the differences in rates for specific causes of death. For the majority of causes of death, the largest differences are found between the rates for divorced and married people. In general, never-married and widowed people have higher rates of cause-specific mortality than married people, alternately occupying the position of the group with the second highest mortality rate. In comparison with the differences found for the total mortality rate, the relative size of the differences in the rates of mortality due to cardiovascular diseases and cancer is somewhat smaller, but it is considerably larger for the mortality rates due to external causes of death (e.g., accident and suicide). [Table 1](#) shows the

age-adjusted relative risks of divorced men and women compared to married men and women for total mortality and mortality from a number of specific causes of death.

Morbidity

More recently, differences in morbidity, short-term disability, and health-care use among marital status groups have been studied. Morbidity differences largely have patterns similar to mortality rate differences: married people have the lowest rates, divorced people have the highest rates, and never-married and widowed people have rates in between. The size of the differences among marital status groups is generally larger for indicators of subjective health (e.g., self-perceived general health and subjective health complaints) than for indicators of objective health (e.g., chronic diseases) and is larger for mental than for physical health.

Morbidity differentials are by and large reflected in the patterns for health-care use and short-term

disability. Widowed and divorced people have higher rates for physician contacts, hospital admissions, and use of medicines and report more bed days and days of restricted activity than married people. Never-married people, however, seem to have a lower health-care use and less bed disability days than married people, despite their higher morbidity rates.

Theories about the Explanation

Several explanations have been suggested for the association between marital status and health. First, it has been put forward that the association might be due to data errors and thus be an artifact. Although data errors might explain part of the association between marital status and health found in earlier studies, more recent studies have shown convincingly that there are genuine health differences among marital status groups. Other explanations that have been proposed can be grouped into two main theories: selection theory and social causation theory. According to selection theory, the relatively good health of married people is the result of the selection of healthy people into and unhealthy people out of the married state. According to social causation theory, marriage has a health-promoting or a health-protective effect, whereas the unmarried state has adverse health effects. Thus, in selection theory, health status precedes marital status; in social causation theory, marital status precedes health status. A graphic representation of these explanations is shown in [Figure 1](#). In order to establish whether or to what extent health differences precede differences in marital status or vice versa, longitudinal data are required. Selection theory and social causation theory are not mutually exclusive, and it is generally accepted that a combination of

Table 1 Relative risks of divorced men and women compared to their married counterparts in the Netherlands, 1986–1990^a

	<i>Divorced men</i>	<i>Divorced women</i>
Total mortality	1.6	1.5 ^b
Cardiovascular diseases	1.5	1.4
Cancer	1.2	1.3
External causes	3.8	3.0
Infective diseases	2.2	2.1
Cirrhosis of the liver (with mention of alcohol)	9.1	6.0
Diabetes mellitus	2.2	1.4

^aSource: Statistics Netherlands.

^bFor example, a relative risks of 1.5 means that the mortality rate of divorced women is 1.5 times that of married women.

Figure 1 A representation of the explanations for health differences among marital status groups. →, social causation; -.->, selection.

selective and causal factors are responsible for the observed health patterns in marital status groups.

Selection on Health and Determinants of Health

According to selection theory, the relatively good health of married people is the result of the selection of healthy people into and unhealthy people out of the married state, thus increasing the relative amount of unhealthy people in the unmarried states. A distinction can be made between direct selection and indirect selection. In direct selection, health itself is the selection criterion; in indirect selection, the determinants of health are the selection criteria.

The process of selection could occur with regard to first marriages as well as other marital transitions (divorce, bereavement, and remarriage) and could cause the health differences by marital status in several ways. Selection in partner choice is the most straightforward mechanism: unhealthy people may be less attractive marriage partners and thus may either not be chosen or, if illness develops during marriage, might be discarded as marriage partners. Selection may also operate through assortive mating, the fact that people generally tend to marry partners with traits that they themselves possess, such as physical attractiveness. Assortive mating could also include health status and does not so much influence whether a person marries as whom the person marries. If, indeed, unhealthy people are more likely to marry unhealthy others, we could find that unhealthy married people are more likely to become widowed because their unhealthy partner is at greater risk of mortality. In addition, it is conceivable that relationships in which both partners are unhealthy are more stressful and therefore more prone to dissolution. Finally, with regard to the transition from the married to the widowed state, selection may also operate through processes independent of partner choice due to health considerations, for instance, through both spouses developing health problems after marriage for reasons such as a joint unfavorable environment (e.g., shared material deprivation or unhealthy behaviors). In this case, the health differences between married and widowed people are not caused by the conditions of widowhood itself (social causation) but are, instead, based in already existing health differences between those who will become widowed and those who will remain married (selection).

Direct Selection

It has been demonstrated in several longitudinal studies that direct selection is operative in marital

transitions. However, the evidence is still partial and sometimes inconsistent. There are indications that the presence of disease decreases the marriage probabilities of never-married people and increases the divorce probabilities of married people. It has also been found that direct selection might be able to explain a considerable part of the health differences among marital status groups. However, other studies have been unable to demonstrate selection effects, and sometimes even evidence for adverse selection was found (i.e., that healthier people were less likely to marry).

Indirect Selection

As stated earlier, selection may operate not only through the exclusion of unhealthy people from marriage (direct selection) but also through selection on a wide range of determinants of health (indirect selection). The determinants of health that may operate in this way are, for instance, socioeconomic status, physical appearance (e.g., body length and obesity), and health-related habits (e.g., alcohol consumption). Research has demonstrated that indirect selection is indeed operative in marital transitions and that its direction is mostly, but not always, in accordance with the health differences observed among marital status groups. Adverse selection occurs, for instance, with regard to educational level among women – people with a higher educational level have more favorable health outcomes than those with a lower educational level, but women with a high educational level are overrepresented among never-married and divorced women.

Social Causation, Intermediary Factors, and Biological Pathways

According to social causation theory, health depends on marital status. Marital status may, on the one hand, affect the etiology of health problems: the married state may prevent people from becoming ill, whereas the unmarried state may be the cause of a decline in resistance to diseases. Marital status may, on the other hand, once health problems have developed, affect the course and outcome of the disease. Ample evidence from longitudinal studies shows that differences in marital status are associated with subsequent health differences; thus social causation mechanisms explain (part of the) health differences among marital status groups. The effect of marital status on health is not assumed to be a direct effect but to be intermediated by psychosocial factors (e.g., stress and social relationships), material circumstances (e.g., financial situation and housing conditions), and health behaviors (e.g., smoking and alcohol consumption).

Psychosocial Factors

Psychosocial stress is related causally to illness and mortality. Lazarus and Folkman defined psychosocial stress as “a particular relationship between the person and the environment that is appraised by the individual as taxing or exceeding his or her resources and endangering his or her well-being.” Psychosocial stress varies among marital status groups. First, bereavement and divorce are stressful life events in themselves. On the social readjustment rating scale of Holmes and Rahe, a scale of 43 life events ordered on the basis of the assumed intensity and length of time necessary to accommodate to the life event, bereavement and divorce rank first and second, respectively. Understandingly, the loss of a beloved person is an important source of stress itself. Feelings of failure, lowered self-esteem, and sense of incompetence, which are often experienced by divorced people, also evoke stress. Furthermore, the many concurrent changes in the lives of bereaved or divorced people, such as lowered income, change in parental responsibilities, forced move to other housing, or the loss of familiar activities and habit systems, also contribute highly to the total amount of stress experienced.

Second, the differences in psychosocial stress among marital status groups are also caused by mechanisms other than the stressful character of the event of bereavement or divorce. Negative societal attitudes toward the marital status a person occupies can be a source of stress. Although societal attitudes toward alternatives to marriage have become more liberal in recent years, prejudices and stereotyped images of never-married people and divorced people still exist. Uncertainty about social roles is also a source of stress, and certainty about social roles differs according to marital status. Marriage provides people with clear and socially acceptable roles, whereas divorce lacks clearly defined norms.

Other psychosocial factors may also contribute to the effect of marital status on health. Several aspects of social relationships are associated with health status and differ among the marital status groups. First, social integration (the existence and quantity of social relationships) is related directly to health. Psychological and sociobiological theories suggest that the mere presence of, or sense of relatedness with, another organism may promote health through relatively direct motivational, emotional, or neuroendocrinal effects. Married people are, on average, more socially integrated for several reasons: they have at least one social tie in their spouse; their children constitute additional social ties, which most never-married people lack; and their social network is expanded with the social ties of their spouse.

Consequently, the loss of a spouse also means a break in the social network.

Second, social support (the functional nature or quality of social relationships) has been found to be related directly and indirectly to health. With regard to the latter, social support is assumed to buffer the negative health effects of stress, thus modifying the relationship between stress and health. In this case, social support has no beneficial effect on the health of people who experience little stress, but the beneficial effects of social support increase with increasing stress. Social support is the aid that is transmitted between social network members. A distinction is often made between emotional and instrumental support. Emotional support includes expressions of affection, admiration, respect, or affirmation; instrumental support is the provision of advice, information, or more practical assistance. The availability and quality of social support differ by marital status. Partner relationships are, in general, more supportive than are other types of relationships. This also means that in cases of bereavement or divorce an important provider of social support is lost.

Finally, differences in social relationships among marital status groups result in differences in social regulation and control. Married people experience more social control; wives, in particular, try to influence their spouses' health behaviors. Furthermore, married people have a more regulated life, which facilitates health-promoting behaviors such as proper sleep, diet, and exercise; the moderate use of alcohol; the adherence to medical regiment; and seeking appropriate medical care.

Material Circumstances

Differences in material resources among marital status groups constitute another intermediary of the relationship between marital status and health. People who share a household profit from economies of scale in the purchasing and use of housing and other goods and services. In addition, changes in marital status are often associated with large changes in material resources. Bereavement and divorce are, especially among women, often accompanied by a decline of their financial situation and, consequently, a deterioration in other structural living circumstances (e.g., housing). This is most obvious in situations in which the husband is the sole wage earner. However, even in cases of double incomes the wife is likely to be worse off financially after divorce or bereavement. Women are generally married to men of a higher or equivalent educational level, and in many countries men earn on average more than women of an equivalent educational level earn. The fact that the material

situation of women generally deteriorates after a divorce does not necessarily imply that men gain materially from divorce. In a divorce, possessions are divided between the former spouses, the ex-husband might be obliged to pay alimony, and economies of scale are lost. This might put divorced men in a materially disadvantaged position compared to married men. Widowed women are generally better off financially than divorced women, even with comparable levels of household income, because divorced women lose their house and must divide assets with their ex-husband, whereas widowed women more often keep the family home and other financial assets intact.

Health Behaviors

Differences in health behaviors among marital status groups are also seen as an intermediary of the association between marital status and health. Marriage often has a deterrent effect on negative health behaviors, such as smoking, excessive alcohol consumption, substance use, and other risk-taking behavior, and marriage promotes an orderly lifestyle. Differences in sexual and reproductive behavior among the marital status groups have been mentioned as explanations for differences in mortality rates from several malignant neoplasms – the excessive mortality rate among never-married women from breast cancer, uterine cancer, and ovarian cancer; the higher mortality rate among divorced women from cervical cancer; and the lower mortality rate among never-married men from prostate cancer.

Finally, differences in the use of health services among marital groups have been mentioned (e.g., married people are more inclined to use preventive health services) and in compliance with required prolonged treatment (married people are more willing to undertake the required treatments for diabetes mellitus and tuberculosis).

Interrelationships between Intermediary Factors

Psychosocial factors, material circumstances, and health behaviors have been mentioned as possible intermediary factors in the effects of marriage on health. However, the effects of marriage on health through intermediary factors cannot be viewed as three independent pathways. Several interrelationships could exist among the three intermediary factors. In the conceptual model of these interrelationships is shown in [Figure 1](#), marital status is not assumed to have a direct effect on health behavior but to influence health behavior only indirectly through psychosocial factors and material conditions.

Psychosocial factors may have direct health effects or may operate through an effect on health behaviors.

Unmarried people experience higher levels of psychosocial stress. Cigarette smoking and alcohol consumption are palliative coping responses to psychosocial stress. In addition, social support is important in health behavior changes; partner support, for instance, is beneficial to smoking-cessation maintenance. Finally, the more regulated life of married people facilitates healthy behaviors, and married people attempt to influence the health behaviors of their spouses.

Also, the material circumstances associated with marital status may have direct health effects, increase psychosocial stress, or operate through changes in health behaviors. With regard to the latter, unhealthy eating habits and a lack of recreation possibilities could, in part, be determined by an individual's financial position.

Evidence from several studies shows that psychosocial factors, material circumstances, and health behaviors act separately as intermediary factors in the relationship between marital status and health. The relative importance of these three groups of intermediary factors has been addressed only recently. Tentative results suggest that psychosocial factors are the most important intermediary factor in health differences between marital status groups among men, whereas material circumstances constitute the major intermediary factor of health differences among women.

Pathways of Intermediary Factors to Health

The effects of health behaviors such as smoking, alcohol consumption, obesity, and lack of physical activity on health are relatively well known. For instance, smoking is, in the long term, associated with cardiovascular diseases, chronic obstructive lung diseases, and many malignant neoplasms such as cancer of the lung, bronchus, trachea, larynx, pancreas, and bladder. Excessive alcohol consumption is associated with diseases of the liver, stomach, and central nervous system and is related to external causes of death, such as traffic accidents and suicide. Obesity and lack of physical exercise are both associated with cardiovascular diseases and conditions of the locomotor system; obesity is also associated with the development of non-insulin-dependent diabetes mellitus.

There is also a considerable amount of research on the relationship between psychosocial stress and health. Stress may cause direct physiological changes in the endocrine, immune, and autonomic nervous systems. Evidence shows that these physiological changes increase susceptibility to infectious diseases, cancer, and cardiovascular diseases. It has also been suggested that marital status, mediated by psychosocial stress, enhances susceptibility to diseases in

general rather than having specific etiological effects. This theory of generalized susceptibility might explain why marital status is associated with many apparently different causes of disease and death.

The direct links between social relationships and health are more speculative. Evidence suggests that biological and psychological mechanisms are involved. A variety of studies of animals and humans suggest that the mere presence of, and especially affectionate physical contact with, another similar or nonthreatening organism reduces cardiovascular and other forms of physiological reactivity. The psychological mechanisms are related to, but partially independent of, the biological mechanisms and might, for instance, be affective in nature (if there is a basic human need for relationships or attachments, people will feel better psychologically when that need is fulfilled, with physiological consequences).

The direct health effects of material circumstances (i.e., health effects not mediated by psychosocial stress or health behaviors) are also of a more speculative nature. In previous centuries, poverty might have been the cause of starvation, death from hypothermia, or increased susceptibility to infectious diseases because of undernourishment. However, the contribution of these causes of death to overall mortality are minimal in current Western societies. However, it is conceivable that unfavorable material circumstances still increase risks for respiratory infections or the transmission of infectious agents through effects on living conditions (damp houses, presence of fungal mold, and crowding). The results of studies on this subject are inconclusive, however. The health effects of material circumstances are presumably mediated mainly by changes in psychosocial stress and, to a lesser extent, by changes in health behaviors.

A final comment with regard to the social causation theory is that we should keep in mind that marital relationships are not always health enhancing. Marital relationships may also have negative health effects,

whereas divorce may have positive health effects. Marital problems are a source of stress, and social control in an environment in which hazardous health behaviors are valued could have unfavorable consequences. With regard to the positive health effects of divorce, it has, for instance, been found that people improve their health after divorce, depending on the stress of the marriage. In addition, several studies have reported that unhappily married people are less healthy than divorced people and happy married people. On the average, however, marriage is associated favorably with intermediary factors and with health.

The Relation between Stress and Marriage
Major Models of Stress and Marital Functioning
Specific Types of Stressors Associated with Marital
Functioning
Methodological and Measurement Issues

Glossary

<i>ABCX and double ABCX models</i>	Models of family adaptation that suggest that successful adaptation is a function of the nature of the stressor, the family's resources for coping with the stressor, how they appraise the stressor, and the extent to which the family has experienced an accumulation of stress over time.
<i>Adaptive strategies</i>	Behaviors that spouses and couples use to negotiate and cope with problems or stressors; include skills in communication, problem solving, and provision of social support.
<i>Infidelity</i>	Sexual or emotional unfaithfulness to a spouse.
<i>Infertility</i>	Persistent inability to conceive a child for at least 1 year.
<i>Marital functioning</i>	A broad term that includes how spouses and couples think about, feel about, and behave in their marriage.
<i>Marital stress generation model</i>	A model, adapted from research on unipolar depression, that was designed to explain how marital stressors are created by troubled spouses and then negatively impact the subsequent individual well-being of spouses.
<i>Marriage</i>	The legal union of a man and woman as husband and wife.
<i>Vulnerability stress adaptation (VSA) model</i>	A model of marital outcomes that suggests that marital dissatisfaction results from the interplay among spouses' individual vulnerabilities, stressors the couple must face, and the skills the spouses and couples have for negotiating and coping with stressors.

This article is based on the definition of marriage in the United States as of February 2005. Because this definition may change in time to encompass more

diverse sets of couples, the types of stressors faced by married couples may also change. Marriage is currently defined as the legal union of a man and woman as husband and wife. Recent U.S. census data indicate that approximately 80% of all Americans will marry at some point in their lives. However, more than 50% of all first marriages will end in divorce, and subsequent remarriages are even more likely to end in divorce. Relationship problems are one of the most common reasons why people in the United States seek counseling, and the development of prevention and intervention programs to combat marital distress and dissolution is proceeding rapidly.

The Relation between Stress and Marriage

Most people agree that stress plays a role in marital functioning, and there is clear evidence that stressful events and circumstances can have a negative impact on marriages. One of the difficulties in this field of study arises from problems inherent in defining the relations between stress and marriage. One distinction that must be drawn is whether the stressors are internal or external to the marriage. An external stressor is something that originates outside the marriage, such as unemployment or health problems. An internal stressor is something that originates inside the marriage, such as marital conflict or divergent needs and desires. A second distinction that must be drawn is between effects of stressors on marriage and effects of marriage on stressors. The effects of stressors on marriage are how stressors, either external or internal, influence marital functioning and the quality and stability of the marriage. The effects of marriage on stressors are how marital functioning affects the experience of stressors, again either external or internal. The experience of stressors, in this case, is how well an individual copes with stressors and the impact the stressor has on the individual in terms of his or her own well-being. The field is still expanding its understanding of the bidirectional relationship between stress and marriage, and advances in this domain are likely to follow in the coming years.

Major Models of Stress and Marital Functioning

There are presently three major models that were designed explicitly to explain the relations between stress and marriage.

The Vulnerability-Stress-Adaptation Model of Marital Outcomes

The VSA model was developed to understand precursors to marital dissatisfaction and marital dissolution. Prior to the development of this model, the study of marital outcomes was dominated by a behavioral and social-learning perspective on marriage, which maintains that marital dysfunction arises because couples do not have adequate skills to negotiate their problems. However, many felt that this perspective was limited, particularly because it failed to focus on the individual qualities of spouses and on stressful life experiences that might affect spouses' abilities to interact successfully with their partners. Hence, the VSA model was developed as an integrative perspective that incorporates three factors: enduring vulnerabilities (e.g., individual characteristics such as personality, psychological symptoms, and family of origin experiences) that spouses bring to the marriage, stressful events (e.g., external stressors) that individuals and couples encounter and experience, and adaptive processes (e.g., skills that couples have for communicating, problem solving, and providing support to one another) that may help the couple negotiate and cope with individual and marital difficulties and stressors.

The VSA model suggests that marital dissatisfaction results from the interplay of these three factors, and most directly from repeated experiences with poor adaptation (e.g., poor communication and social support). Once a couple is dissatisfied, it is then at risk for marital dissolution. Stressful life events in the VSA model are seen as factors that impact or interact with a couple's capacity for successful problem negotiation or social support in predicting marital dissatisfaction. For example, stressful life events will lead to dissatisfaction when a couple does not have the adaptive skills to successfully negotiate or cope with the stressor. Stressful life events might also erode a couple's capacity for successful coping (i.e., successful adaptation) if the events are severe enough. The VSA model also suggests that stressful life events can be created or exacerbated by spouses' enduring vulnerabilities and the inability to successfully negotiate problems. For example, people with certain personalities might be particularly prone to generating stress, and couples with poor communication skills may inadvertently contribute to the stressful events with which they then must contend. Hence, in this model, stressful life events play a very important role in marital dissatisfaction and dissolution.

Research largely supports the hypothesis that good adaptive processes moderate the impact of life stressors on marital functioning. This is particularly true

for the moderating role of social support. Some research also indicates that problem-solving behaviors moderate the association between stressors and marital functioning. For example, Cohan and Bradbury found that levels of stressful life events were associated with emotions and behaviors displayed while couples were discussing marital problems. Furthermore, the association between life events and later marital satisfaction was moderated by problem-solving behavior. Higher levels of life events were associated with lower levels of marital satisfaction in couples when, for example, wives did not effectively express their anger about marital problems.

The ABCX and Double ABCX Models of Family Stress

Hill's 1949 ABCX model of family adaptation has largely guided family stress theory. His theory was based on his study of servicemen separated from their families during World War II, but the model is sufficiently general to be considered applicable to all families and marriages. Hill suggested that stressors have the potential to produce change in the family system and that family adaptation differs in response to stressors. He proposed that family adaption (X) was a function of the nature of the stressor (A), the family's resources (B), and the family's appraisal of the stressor (C). Regarding the nature of the stressor, the stressfulness of an event depends on exactly what the nature of the event is – some events are inherently more stressful than others. Family resources are similar to adaptive processes and enduring vulnerabilities in the VSA model. For example, family resources may be material, such as income; intrapersonal, such as education or family of origin experiences; or interpersonal, such as communication skills or family cohesion. More resources should minimize, and fewer resources should maximize, the negative consequences of stressful life events. The family's appraisal of the stressor determines how the family views the stressful life event. Families who view the event as a threat should fare worse than families who view the event as a challenge.

The Double ABCX model expands the ABCX model by including a mechanism to explain the development of family adaptation or distress over time. That is, whereas the ABCX model focuses on adaptation at one point in time in response to a concurrent stressor, the Double ABCX model includes the accumulation of stress over time as a predictor of longer-term adaptation. The notion is that family crises do not occur in isolation. They occur in conjunction with other preexisting stressful circumstances, and they initiate new stressful circumstances. Thus, the Double

ABCX model encompasses the accumulation of stressful circumstances (aA), existing resources and additional resources developed by responses to earlier stressors (bB), appraisals of the original stressor and the aftermath of the family's attempt to deal with it (cC), and longer-term family adaptation (xX). These two models have gained much empirical support in studies of families with diverse stressors, including families coping with wartime separations and families coping with children who have mental disorders. These models have also been used to inform the assessment and treatment of children and families facing severe life stressors. Although not explicitly designed to understand stress in marriage, these models have clear applications to marital outcomes in that when successful adaptation is not achieved, marital distress and dissolution may follow.

The Marital Stress Generation Model

The marital stress generation model was designed to explain how marital stressors (internal stressors) are created by spouses and how marital stressors impact the individual well-being of spouses. Hence, it differs from the other two models that focus on external stressors and how couples and families cope with them. The marital stress generation model proposes that symptomatic spouses (e.g., spouses with depressive symptoms) perceive their partners negatively and are deficient in their capacity to communicate with, negotiate with, or support their partners. These negative perceptions and deficiencies lead spouses to experience more stressors within their marriage, and these stressors subsequently maintain or exacerbate the symptomatic spouse's symptoms.

The marital stress generation model developed out of the stress generation model of unipolar depression, which stated that depressed people contribute to the occurrence of interpersonal stressors, which then contribute to further depression. Research has consistently supported this model and has suggested that a stress-generation process may not be specific to depression. Research on the marital stress generation model supports the model, at least for wives. For example, Davila et al. found that wives with depressive symptoms expect their husbands to be critical of them and then solicit and provide support in a negative manner when interacting with their husbands. This behavior leads to increases in marital stress, which in turn leads to increases in wives' depressive symptoms. Hence, the model describes how marital interactions (e.g., involving the provision and receipt of social support), marital stress and individual well-being can affect one another and keep spouses mired in a cycle of marital dysfunction and distress. In a

similar vein, some researchers hypothesize that in maritally discordant wives uncertainty about the future of the relationship and ongoing concerns about spousal disagreements may elicit and further perpetuate anxiety symptoms, and that reduced positive reinforcement from spousal interactions and helplessness about the ability to change the relationship may elicit and perpetuate depressive symptoms.

Summary

The three models described here address different types of stressors and different segments of the stress-marital functioning association. However, they have at least one significant commonality in that they all focus on the adaptive strategies used by couples to negotiate problems or to support one another. This highlights the fact that the manner in which couples cope with stressors is critical to their ultimate marital outcome.

Specific Types of Stressors Associated with Marital Functioning

A number of specific types of stressors and their association with marital functioning have been studied. Samplings of the major stressors are presented. Not all of these programs of study were conceived of as research on stress and marriage, but, by their nature, the variables they examine are stressful events and fit within the stress paradigms just described. Initial investigations of many of these stressors focused on direct associations between the stressor and marital functioning. Research has moved toward more integrated models, as described, particularly with respect to how the manner in which couples negotiate or cope with stressors affects associations between stress and marital functioning. Although such knowledge is expanding, further research on the mechanisms of the association between stress and marital functioning is still necessary.

Work-Related Stressors and Unemployment

Work-related stressors and unemployment (especially those ensuing financial hardship) are consistently shown to be associated with poorer marital and family functioning. Job loss and unemployment decrease the individual well-being of spouses, decrease marital satisfaction, and increase marital dissolution. Consistent with the models described earlier, research suggests that these negative effects can result from poor adaptation within the family (e.g., increased conflict and poor social support) and from increased depression among spouses. For example, financial strain can lead to increases in depressive symptoms, which lead

to reductions in spousal support and increases in marital distress. Work-related stressors show similar associations. For example, couples have more negative marital interactions on workdays that are reported as more stressful and when daily workload is high. Different types of jobs may also be more or less stressful. For example, shift work or jobs involving separations may be more stressful for some couples than are other types of work. The negative impact of long working hours on marriage is receiving greater attention as the length of the typical work week increases. Related to this, a number of studies have examined differences between blue-collar and white-collar workers facing job stress, and they suggest that blue-collar marriages may be at greater risk than white-collar marriages, possibly because of the different strategies they use to cope with job stress. However, much variance exists within blue- and white-collar jobs. In summary, there is clear evidence that work-related stress, and the manner in which couples negotiate it, can have a serious negative impact on marriage.

Military Service

Military couples and families often deal with a unique set of stressors, such as frequent relocation, relationship maintenance during separation, reunion, and numerous other factors above and beyond those dealt with by nonmilitary couples. A number of studies, many deriving from early tests of the ABCX model of family stress, indicate an association between aspects of military service and marital functioning. For example, wives' perceptions of marital adjustment declined during husbands' military-related absences, and wives and children reported increased emotional distress during absences. In addition, higher levels of marital quality before husbands' military-related absences led to more successful family reintegration at the end of the absence. The higher levels of military life stress are also associated with lower levels of general well-being and global life satisfaction among military wives. Hence, being married to a man in the military and the stressors that come along with that may have negative outcomes for wives, although this is likely to be moderated by family adaptation. Newer lines of research are investigating the role of military women as well as couples in which both partners serve in the military. The implications of such roles for marital and familial relationships are still in an early stage of examination.

Health Problems

A relatively large literature has indicated that health problems are significant marital stressors and that

marital quality has a significant impact on health outcomes. Longitudinal studies indicate that unhappy marriages are associated with morbidity and mortality. Although the relationship between poor marital quality and health problems is bidirectional and thus difficult to disentangle, examining the consequences is nonetheless of paramount importance. Numerous health problems have been studied, including chronic pain; cancer; cardiac disease; pulmonary disorders; renal, endocrine, and gastrointestinal disorders; and neurological disorders. In general, this research indicates that health problems both affect and are affected by marital functioning. Furthermore, social support may play an important stress-buffering role for individuals and couples. Coronary heart disease is one of the most well-researched stressors, and it provides a good example of how health problems and marital functioning can be related. For example, research has indicated that spouses of cardiac patients have higher levels of psychological distress and more marital tension postrecovery. Research has also indicated that spousal support (e.g., intimacy, and emotional and instrumental support) is associated with better outcomes for coronary heart disease patients, including lower mortality rates, whereas marital discord and conflict leads to worse outcomes. The association between coronary heart disease and marital functioning is considered so important that relationship-based interventions for cardiac patients and their partners are now emerging. Of course, different health problems may pose different challenges for individuals and couples. Hence, the associations between health stressors and marital functioning may be different depending on the health problem studied. Abrasive marital interactions appear to have negative consequences on endocrinological and immunological functioning. Studies examining negative behaviors during marital conflict have found that such activities are associated with increased levels of epinephrine, norepinephrine, growth hormone, and adrenocorticotrophic hormone (ACTH), as well as greater immunological change over the following 24 h. Wives appear to be more reactive physiologically to marital conflict than husbands. Longitudinal studies have further supported such findings, with higher levels of stress hormones in newlyweds foreshadowing marital distress and dissolution 10 years later.

Infertility

Infertility is a significant stressor that affects approximately 10% of couples, according to recent estimates. Research suggests that infertility can have numerous negative effects for women and men, including lowered self-esteem, increased depression and

anxiety, and feelings of guilt and shame. Some of these negative effects may be even more prominent among women. For example, studies have found that associations exist between infertile women who desire children (and have no social or biological children) and substantial and significant long-term psychological distress. Clinical and anecdotal evidence suggests that infertility also negatively affects marital satisfaction and marital functioning, particularly sexual satisfaction. The diagnosis, investigation, and/or management of infertility may interact with a couple's sexuality and sexual expression by exacerbating sexual problems, or the sexual problems themselves may be a contributory factor in childlessness. It is certain that couples dealing with infertility are faced with many issues that can strain a marriage beyond sexual difficulties alone, such as financial difficulties (from the high costs of fertility treatments) and reconceptualization of future plans and social roles. However, the empirical data indicate that couples with fertility problems are no more dissatisfied with their relationships than are other couples. In addition, there is evidence that infertility has positive effects on some couples. Successful coping with infertility can result in increased commitment and closeness. Hence, the effects of infertility on marital outcomes may depend on how couples adapt to or cope with the stressor. In line with this, data indicate that couples will fare worse when spouses have incompatible ways of coping with infertility.

Transition to Parenthood

Numerous studies have suggested that marriage suffers during the transition to parenthood. For example, marital satisfaction tends to decline and marital problems and conflict can increase, particularly in wives. However, research that contradicts these findings also exists. Methodological issues are problematic in prior studies showing decline; there are distortions such as the assessment of spouses during the third trimester of pregnancy and the failure to include comparison groups of couples at similar points in marriage who were not having children. Studies that include comparison groups and that assess spouses before, during, and after pregnancy have failed to find differences between the couples who were transitioning to parenthood and those who were not. There is some evidence, however, that marital factors affect which couples will fare better or worse during the transition to parenthood. For example, existing marital problems may lead spouses and couples to experience a more stressful transition, and, to the extent that spouses' child care and housekeeping

expectations for their partners are not met, couples may view their marriages more negatively. Hence, the transition to parenthood may not be equally stressful for all couples, but may instead depend on how couples negotiate the transition.

Psychopathology

Much research indicates that psychopathology is intrinsically linked with marital functioning. Although psychopathology is conceived of as an enduring vulnerability in the VSA model of marital outcomes and as a cause and an outcome of marital stress in the marital stress generation model, it may be reasonable to also consider psychopathology as a stressor, particularly when a spouse is in the active phase of a disorder. Various types of psychopathology, including depression, substance abuse, anxiety disorders, and schizophrenia, are associated with significant marital dysfunction and divorce. As such, they are stressors that have major implications for marital outcomes, largely because they interfere with important aspects of marital functioning. For example, skillful communication, adaptive emotion regulation, and the ability to be physically and emotionally available and supportive are important to good marital outcomes, but they are often impaired by psychopathology. Research consistently suggests that greater levels of psychopathology are associated with lower levels of marital satisfaction. It has also been found that depression in one spouse is significantly associated with lower marital satisfaction in both spouses. The association between psychopathology and poor marital functioning is so prominent that forms of marital and couple therapy are used to treat many disorders, highlighting the importance of examining the effects of psychopathology on both partners.

Infidelity

Infidelity is an important internal marital stressor that has recently garnered a great deal of attention. Although a paucity of empirical research on this stressor currently exists, both clinicians and scholars have recognized the significance of infidelity to couples. For example, Cano and O'Leary found the discovery of infidelity to be associated with increased levels of clinical depression in the noninvolved spouse. Given the significant negative role of psychopathology in marriages, as noted in a prior section, these findings highlight the importance of investigating infidelity as a marital stressor. Currently, researchers are investigating the differing effects of emotional versus sexual infidelity on wives and husbands. Findings are mixed as to whether gender differences exist

in response to different types of infidelity. Present research has investigated differences in husbands and wives in terms of the amount of distress caused or the likelihood of forgiveness depending on the type of infidelity. It appears that men's distress is primarily predicted from the type of infidelity (greater distress from sexual infidelity than emotional), whereas women's distress is predicted from a number of factors (e.g., relationship commitment and whether the person the husband is having the affair with is a new person vs. an ex-partner). Relationship commitment appears to be highly associated with the likelihood to forgive for both husbands and wives. However, more research is needed on the interactions between gender differences and the type of infidelity.

Ethnic Differences in the Relations between Stress and Marriage

Research on ethnic differences in the association between stress and marriage is still in its early stages, but indicates that couples of varying ethnicities are likely to experience different types of stressors consistent with their ethnic/cultural backgrounds. These stressors may be altered or amplified in couples of differing ethnicities and cultural backgrounds. Ethnic minority couples also face different stressors at a societal level than do Caucasian couples (e.g., stereotyping and stigmatization), suggesting that couples of different ethnicities may face stressors that present unique challenges to the success of their marriages. Much of the existing research focuses on differences between Caucasian and African American couples and families; however, there is an increasing trend toward including Latino and Asian couples and families. In general, research indicates some similarities between couples of various ethnicities but also some potentially important differences. Stressors related to financial hardship and social networks may play a particularly important role in African American and Latino marriages. Because of these sorts of findings, some authors are now calling for a more comprehensive model of marital outcomes for various ethnic minority couples, similar to the models described earlier, that include the role of stressors and how couples adapt to them. A great deal of additional research is necessary before the ethnicity-specific associations between stressors and marital outcomes for all groups are more fully understood. Research on interracial marriages and their potentially unique stressors is also garnering an increasing amount of attention. Such research suggests higher levels of marital challenges due to lack of cultural understanding, racial pressure, and lack of familial support. However, much more research is needed in this area.

Methodological and Measurement Issues

The study of stress in general has been fraught with measurement and methodological problems, and many of these problems emerge in the study of stress and marriage. For example, both external and internal stressors typically have been assessed using self-report measures. People are asked to report whether a stressor has occurred and how much stress or negative impact was associated with the occurrence of the event. At issue here is the extent to which people are reliable reporters, particularly when assessing amount of stress or negative impact. These reports can be biased by mood. Hence, distressed or unhappy spouses may report higher levels of stress and negative impact than nondistressed spouses, and this may artificially inflate associations between stress and poor marital functioning. One solution to this problem draws on the contextual threat procedures developed by George Brown and colleagues. Participants are interviewed and interviewers or coders make ratings of objective stress, as opposed to spouses' subjective stress ratings. This procedure is used frequently in the study of stress and psychopathology, and it could easily be applied to studies of marriage and stress. However, it is a time-consuming procedure. Another option is the use of daily diaries. Although such methods rely on self-report data, if we are interested in data obtained through self-report, such as examining each partner's account of various life events, daily-diary information may prove very useful. Notably, in daily-diary studies there is a dramatic reduction in the likelihood of retrospection because the amount of time elapsed between an experience and the account of the experience is minimized. The recall of the frequency of various stressors and marital interactions, and the immediate response to such events, therefore, may be greatly improved. Another consideration for marital researchers is whether it is the number of stressors that spouses experience or the stressfulness of stressors (e.g., the nature of the stressor) that affects marriage. Similarly, there are numerous types of stressors, including discrete events, chronic strains, and daily hassles, which might affect marital functioning in different ways. Another issue in stress research that applies to marital research is the reliance on retrospective reports of stress. Current models of stress and marriage imply longitudinal associations between the two, which suggests that stressors should be examined prospectively over time. Finally, it may be important to study specific types of stressors individually rather than aggregating unrelated events. All stressors may not show similar associations with marital functioning.

Introduction

Maternal Deprivation Models

Consequences of Maternal Deprivation

Biological Significance

Glossary

Corticotropin releasing hormone (CRH)

A 41-amino-acid peptide and the primary regulator of the pituitary-adrenal system that is activated in response to stressors. CRH also acts as a neuromodulator in corticolimbic and brain-stem areas and, thus, is believed to participate in the coordination of the mammalian neuroendocrine, behavioral, autonomic nervous system, and immune responses to a stressor.

Hypothalamic-pituitary-adrenal (HPA) axis

A system that transduces interoceptive and exteroceptive signals into an endocrine response, culminating in the synthesis and secretion of adrenal glucocorticoids that act throughout the body to mobilize energy substrates such as glucose for use by the individual in escape or fighting.

Maternal deprivation

A neonatal manipulation in which rat pups are briefly handled and separated from the dam for prolonged periods of time ranging from 3 to 24 h. This procedure is typically implemented between postnatal days 1 and 21, with either single or repeated exposures.

Stress hypo-responsive period (SHRP)

A period from postnatal days 3 to 14 when neonatal rat pups show attenuated pituitary-adrenal responses to stressful stimuli that would cause a response in the adult. This period is characterized by low levels of circulating glucocorticoids, although a majority of this steroid is in free form due to the low production of corticosteroid-binding globulin during this age period. It has been postulated that the maintenance of low glucocorticoid levels is necessary during this period for the normal development of the HPA axis and the central nervous system, especially the hippocampus.

Early experience is associated with long-term behavioral, neuroendocrinological, cognitive, and central nervous system (CNS) changes in rodents, guinea pigs, and primates. The specific effects of positive or negative stimuli during the neonatal period are believed to be dependent on the genetic background of the individual, developmental status of the CNS at the time of exposure, duration of the stimulus, type and severity of the experience, and other factors such as the availability of social support. A number of research laboratories have employed the paradigms of neonatal handling and neonatal maternal deprivation as probes of CNS plasticity during the postpartum period. In general, these paradigms exert opposite influences, with maternal deprivation being associated with long-term increases in anxietylike behavior, HPA axis responsiveness to stressors, and changes in the functional characteristics of the central neurocircuits involved in the perception of and response to environmental events. Due to the relative stability of the changes resulting from neonatal maternal deprivation, as well as the ability of antidepressant treatment to reverse these changes transiently, this paradigm has been explored as an animal model of affective disorders.

Introduction

Initial studies in the late 1950s and 1960s by Levine, Denenberg, Ader, and others showed that neonatal handling or infantile stimulation led to long-term adaptations in behavior and the stress response. Subsequently, numerous paradigms of prenatal stress, neonatal maternal deprivation, and isolation rearing have been developed by numerous laboratories to systematically study the effects of adverse early experience on the development of behavior, endocrine function, and the CNS. This review is primarily limited to the effects of neonatal maternal deprivation in the rat. Before introducing the neonatal deprivation models, we provide a brief review of the developmental status of the neonatal CNS, the HPA axis and stress response, and the role of maternal behavior in development.

Central Nervous System Plasticity in the Neonate

Genetic and environmental factors interact to guide CNS development throughout the life span. Although the basic structure and connectivity of the brain are specified by genetic factors, environmental factors

play a key role in programming the patterns and density of connectivity that underlie the individual organism's perception of and responsiveness to its environment. These adaptations occur via a variety of processes, including activity-dependent plasticity and synaptic pruning. Frequently, this plasticity involves neurocircuits mediating the various aspects of the stress response, including the regulation of HPA axis activity.

Because many species spend their lifetimes within a narrow geographical range with respect to their birthplace, this interactive process may provide an adaptive advantage, serving as a mechanism by which an individual organism may optimize its neurocircuitry and develop behaviors appropriate for survival. As illustrated in [Figure 1](#) for the rat, many neurodevelopmental processes continue during and after the neonatal period. Furthermore, many of these processes are sensitive to circulating glucocorticoid hormone levels. Therefore, exposure to adverse conditions during the neonatal period can modulate the CNS developmental process through multiple mechanisms. This postpartum period of increased vulnerability to environmental factors varies among species, depending on the state of CNS developmental maturity at birth.

The Hypothalamic–Pituitary–Adrenal Axis and Regulation of the Stress Response

Internal and external stimuli (i.e., stressors) conveying actual or perceived threat, pain, metabolic imbalance, or failure of expectations are processed via widely distributed pathways and converge on the paraventricular nucleus (PVN) of the hypothalamus. Neurons in this structure produce the peptides corticotropin releasing hormone (CRH) and arginine vasopressin (AVP), which are transported to the median eminence nerve terminals and are released into the hypophyseal-portal circulation, the functional link between the CNS and the endocrine system. At the anterior pituitary gland, these peptides stimulate the synthesis and release of adrenocorticotrophic hormone (ACTH) into the systemic circulation. Circulating ACTH evokes the synthesis and secretion of glucocorticoids (cortisol in primates and corticosterone in rodents) from the adrenal cortex, which serve to mobilize energy substrates during stress. Plasma glucocorticoid levels are controlled tightly by glucocorticoid-mediated negative feedback on the secretion of CRH and ACTH by the activation of cytoplasmic mineralocorticoid receptors (MR) localized in the

Figure 1 Developmental processes occurring during the neonatal period in rodents. Maternal deprivation paradigms overlap a significant portion of the stress hyporesponsive period (SHRP). Throughout the neonatal period, myelination, neurogenesis, and apoptosis, as well as synaptogenesis and synaptic pruning, are occurring. All these mechanisms represent targets for epigenetic and environmental modification of the basic genetic plan for CNS development.

hippocampus and septum and/or the activation of cytoplasmic glucocorticoid receptors (GR) located in the adenohypophysis and throughout the CNS.

HPA axis responses are adaptive and essential for survival in adulthood, but may be maladaptive in infancy while the brain is immature. In the normally developing rodent the brain is protected from catabolic and other effects of glucocorticoids due to a reduced sensitivity of the HPA axis to activation during the neonatal period, postnatal days (PND) 3–16, a developmental epoch known as the SHRP. This reduced responsiveness is not absolute and may be overcome by strong stressors, including maternal deprivation.

Role of Maternal Behavior in Postnatal Development

The early environment in many mammalian species is determined largely by the mother. In many primate species, including humans, early interactions between the mother and the infant serve as a template for all subsequent relationships. The neonatal rat is completely dependent on its mother for nutrition, temperature regulation, grooming, and regulation of micturition for the first 2 weeks of life. Alterations in the quality of maternal care have been shown to exert profound and long-lasting influences on the development of stress responsiveness and health in rodent offspring. This dependence and the subtle complexities of maternal behavior led Hofer to postulate the concept of the mother as a hidden regulator of physiological and behavioral development in the rat.

In many mammals, maternal care is quite stereotypic and involves a number of distinct behaviors. Maternal behavior in the rat consists of nest building, retrieval of the pups into the nest, nursing periods associated with an arched-back posture to encourage suckling, and anogenital licking to stimulate urination and defecation. Levine and colleagues showed that particular maternal behaviors modulate the development of the HPA axis at different levels and serve, in part, to reduce the responsivity of the HPA axis beginning a few days after birth and lasting until the pups are more independent.

Maternal Deprivation Models

Rodent Models of Maternal Deprivation

Numerous maternal deprivation models have been developed to study the effects of prolonged separations of infants from their mothers on behavioral and endocrine responsiveness. These deprivation manipulations vary greatly among research groups, ranging from a single 24-h deprivation to repeated maternal deprivation episodes lasting 12, 8, 6, or 3 h from PND

1–2 through PND 14–21. In addition, some paradigms require the isolation of pups from one another during the separation period, whereas in others the pups remain together as a litter during the period of separation.

In an open colony setting, the dam typically leaves her pups for periods of 5–15 min in order to forage for food and water; however, in some cases the dam may be away for periods of 60–180 min. Mimicking these observations, Plotsky and Meaney developed a maternal deprivation model in which Long Evans rat litters were standardized to eight male pups (or four male and four female pups) on PND 2 and then assigned randomly to one of four neonatal rearing conditions during PND 2–14, inclusive: (1) brief handling and 180 min per day of maternal separation (HMS180); (2) brief handling and 15 min per day of maternal separation (HMS15); (3) nonhandled (HMS0); and (4) animal facility rearing (AFR), in which litters were handled twice weekly beginning on PND 4 for cage changing. Bedding material in the home cages was replaced only partially (50%) with clean bedding once per week when the dams and pups were out of the cage (HMS15 and HMS180). In all deprivation studies, the dams were moved to an adjacent cage when they were off the nest in the morning and then the pups were placed in a transfer cage and moved to an incubator in another room. At the end of the daily separation, both HMS15 and HMS180 litters were returned to their home cage, rolled in the native bedding, and then reunited with their dam. All litters were weaned on PND 21–23 and group housed (two to three per cage) until adulthood (> PND 60).

Comparisons have been made between the maternally deprived animals (HMS180) and a control group consisting of nonhandled (HMS0), animal facility-reared (AFR), or handled (HMS15) rats. Despite the wide variations in the maternal deprivation protocols, adult animals that experienced neonatal maternal deprivation typically display high anxietylike behavior and HPA axis hyperresponsiveness, whereas adults that experienced neonatal handling exhibit reduced anxietylike behavior and conserved HPA axis responses to stressors. In this review, the control and experimental groups are presented as in the studies, but it should be kept in mind that the selection of the control group may have a profound effect on the conclusions drawn from the data.

Primate Models of Maternal Deprivation

The majority of nonhuman primate maternal deprivation studies have been performed in rhesus monkeys or squirrel monkeys. The specific nature of the maternal deprivation protocols varies widely in these studies from severe and prolonged maternal

deprivation to less profound periods of deprivation. Maternal separation in primates is associated with increased oral behaviors and other stereotypic movements, anxietylike behavior, cognitive impairment, aggression, deficits in bonding, and exaggerated HPA axis function.

Consequences of Maternal Deprivation

Changes in Maternal Behavior

The dams of pups exposed to the HMS15 protocol exhibited increased maternal behavior, such as licking and grooming of the pups, as compared to the AFR group, whereas prolonged maternal deprivation (HMS180) was associated with reduced and deranged maternal behavior. Dams of the HMS180 group retrieved their pups with a longer latency on reunion and took longer to begin to nurse the pups as well as to lick and groom them. This decreased maternal behavior was largely responsible for the long-term resistance to stress as demonstrated in cross-fostering studies. In support of the role of maternal behavior, Meaney and colleagues demonstrated an inverse correlation between the amount of time the dam spent in licking, grooming, and arched-back nursing of her pups and subsequent adult stress responsiveness. Furthermore, the importance of anogenital licking for the development of the normal HPA axis stress response has been shown.

Hypothalamic-Pituitary-Adrenal Axis Adaptations

Handled, nonhandled, and maternally deprived rats show distinct and stable differences in their HPA response to stressors as adults, as summarized in Table 1. In adult rats, basal levels of ACTH and corticosterone typically do not differ among the rearing groups described earlier. However, in response to a psychological stressor (e.g., novel environment or air puff startle), exaggerated ACTH and corticosterone responses are apparent in maternally deprived and nonhandled rats as compared to handled or animal facility reared rats. Using a single 24-h period of neonatal maternal deprivation, van Oers and colleagues have shown that the age at which maternal deprivation occurred altered the outcome with respect to HPA axis function. Deprivation at PND 3 resulted in hyperresponsiveness of the pups at PND 20, whereas deprivation at PND 11 resulted in hypo-responsiveness. Similar experiments will be necessary to elucidate the neurocircuits and mechanisms mediating aspects of the overall neuroendocrine, behavioral, and cognitive effects of neonatal maternal deprivation.

Table 1 HPA axis effects of neonatal handling and maternal deprivation as compared to nonhandled rats

Variable	Neonatal handling ^a	Neonatal maternal deprivation ^b
HPA axis function		
Basal ACTH	↔	↔
Basal corticosterone	↔	↔
ACTH stress response	↓	↑
Corticosterone stress response	↓	↑
Dexamethasone resistance	↔	↑
CRH receptor binding		
Paraventricular nucleus	↔	↑
Pituitary	↔	↓
CRH content		
Paraventricular nucleus	↔	↑
Stalk median eminence	↓	↑
CRH mRNA		
Paraventricular nucleus	↓	↑
GR mRNA		
Hippocampus	↑	↓
Paraventricular nucleus	↔	↔
Pituitary	↔	↔
Prefrontal cortex	↑	↓

^aHMS15 (brief handling and 15 min per day of maternal separation).

^bHMS180 (brief handling and 180 min per day of maternal deprivation).

At the level of the hypothalamus, maternally deprived and nonhandled rats show significantly greater expression of CRH mRNA, specifically in the PVN, compared to handled rats. In addition, these rats have an elevated peptide content of CRH and AVP in the stalk median eminence as well as increased CRH and AVP concentrations in the hypophyseal-portal circulation compared to handled rats. Also, maternally deprived and nonhandled rats show increased CRH receptor binding in the PVN compared to handled rats. This latter adaptation may reflect the increased expression of CRHR1-receptor mRNA in the PVN as a consequence of the stress of maternal deprivation. Thus, the brains of these animals exhibit increased CRH as well as potentially increased responsiveness to this CRH.

Impaired glucocorticoid-mediated negative feedback may contribute to the elevated expression of CRH as well as to the exaggerated secretion of ACTH and corticosterone seen in deprived rats, whereas an increased feedback tone may underlie the reduction in stress responsiveness observed in handled rats. The expression of the two types of glucocorticoid receptors is extremely vulnerable to neonatal experience. The type 1 or mineralocorticoid receptor (MR) is a high-affinity receptor that shows a high degree of saturation even under basal conditions. It is believed to be

involved in the maintenance of basal HPA activity. In contrast, the type 2 or glucocorticoid receptor (GR) is a low-affinity receptor that becomes activated in the presence of elevated levels of glucocorticoids typical of stress. As adults, the density of hippocampal GR binding sites in the experimental groups is handled = AFR > nonhandled > maternally deprived; the levels of GR mRNA follow a similar pattern. An increased expression of GR in the hippocampus and prefrontal cortex may increase the negative feedback tone on the HPA axis, thus providing a mechanism by which handled rats dampen their stress response. Conversely, the reduction of hippocampal GR in maternally deprived rats may, in part, explain their HPA axis hyperresponsiveness to stressors. Reports also indicate that hippocampal MR mRNA levels are increased in HMS180 maternally deprived rats, perhaps accounting for the normal circadian trough and peak ACTH and corticosterone levels in these animals. These changes in GR and MR binding and expression are apparent from at least PND 21 in the HMS180 model.

However, in response to 24 h of maternal deprivation on PND 3, Levine's group found decreased binding for both MR and GR in the CA1 region of the hippocampus in males at PND 48. No changes were observed in binding of the MR in females at PND 48 or of mRNA for either MR or GR at PND 60. When deprivation was applied on PND 11 and the brains collected the next day, one study showed a decrease in both MR and GR mRNA in CA1, whereas another study showed a decrease only in the MR mRNA in CA1 and no changes in the GR mRNA. Thus, although these studies confirm the high degree of plasticity of the glucocorticoid receptors in the brain in response to early experience, the actual effects of maternal deprivation seem variable over time. Studies of the time sequence in glucocorticoid receptor expression changes in response to maternal deprivation are needed to sort these out among maternal deprivation paradigms.

Behavioral Consequences

Stress has long been associated with increased anxiety- or fearlike behavior. Using multiple tests of these behaviors (e.g., elevated plus maze, novel open-field locomotion, defensive withdrawal, and acoustic startle), many groups have shown that maternal deprivation is associated with increased anxiety- and fearlike behavior beginning in the neonatal period and persisting throughout adulthood.

When placed in a brightly lit, novel open field, rats initially spend more time near the walls and show reduced locomotor activity. HMS180 maternally deprived rats continue to display neophobia long after the AFR and HMS15 animals have habituated to the

novel environment. Similar results were found in an open-field exploration test as well as in the latency to eating in a conflict test following overnight food deprivation, suggesting a heightened fearfulness in maternally deprived rats exposed to a novel arena.

In the defensive withdrawal test, HMS180 rats show an increased latency to exit from a safe compartment into the open-field arena and demonstrate an increased number of reentries into the cylinder as well as a greater total amount of time spent in the cylinder compared to AFR and HMS15 rats. Similarly, in the elevated plus maze, maternally deprived rats spent less time in the open arms compared to either handled or AFR rats. Nonhandled rats show a level of anxietylike intermediate between maternally deprived and handled rats in these tests. Thus, it appears that maternally deprived rats show greater anxiety and neophobia than do handled (HMS15), nonhandled (HMS0), or normally reared (AFR) rats.

Early experience can also affect an adult animal's cognitive performance. Infantile handling has been shown to prevent cognitive impairments as the animal ages. At 24 months, but not at 12 months, handled rats learn to find a hidden platform in the Morris water maze faster than nonhandled rats. This may be due to less exposure to glucocorticoids throughout the animals' life because elevated levels of these stress hormones are related to cognitive impairments. It has been hypothesized that maternally deprived rats should be impaired on tasks of learning and memory. Data from the authors' laboratory support this hypothesis; middle-age (120 days) maternally deprived rats show a slight, but significant, impairment on the learning of the Morris water maze.

Overall, these behavioral observations provide compelling support for the thesis that maternal deprivation during the neonatal period increases anxiety- or fearlike behavior that persists throughout adulthood. Thus, sensory experiences encountered during a critical window of development, particularly those associated with mother-infant interactions, significantly affect individual perception of the environment and responses to it throughout life. It is postulated that this process arises through a combination of stimulus-induced plasticity during postnatal development, activation of extrahypothalamic CRH neurocircuits, and glucocorticoid effects mediated through a cascade of transcriptional changes in critical sensory and limbic systems.

Extrahypothalamic Effects

Considering the effects of maternal deprivation on behavior and endocrine responses to psychological stressors, it would not be surprising to find a number of adaptations in the CNS, especially in systems

involved in the regulation of stress and fear. Studies in the HMS180 maternal deprivation paradigm have shown that maternal deprivation and handling affect extrahypothalamic CRH systems, GABA and benzodiazepine pathways, and norepinephrine circuits as outlined in Table 2.

The involvement of extrahypothalamic CRH systems is particularly salient because these circuits appear to coordinate the neuroendocrine, behavioral, sympathetic nervous system, and cognitive responses to stressors. Furthermore, there are substantial interactions between these CRH-containing neurocircuits and brain-stem noradrenergic systems. CRH mRNA levels in the central nucleus of the amygdala and the bed nucleus of the stria terminalis were increased in HMS180 maternally deprived rats and decreased in HMS15 handled rats compared to nonhandled rats. The CRH mRNA levels in these brain regions of the HMS15 rats were equivalent to those of animal facility-reared animals.

These CRH-containing pathways project to brain-stem areas such as the locus ceruleus, where CRH activates locus ceruleus noradrenergic neurons. This stress-induced activation may serve to increase autonomic nervous system information flow, enhance vigilance behavior, and provide additional drive to the HPA axis. In addition, the apparent reduction in α_2 -adrenergic receptor binding in the locus ceruleus and nucleus of the solitary tract implies that, once activated, the firing rate of the locus ceruleus neurons may be difficult to shut off. Interestingly, HMS180 maternal deprivation was also associated with decreased central benzodiazepine (CBZ) receptor binding in the locus ceruleus and the nucleus of the solitary tract compared to handled rats. Thus, increased CRH and reduced CBZ, GABA_A, and α_2 -adrenergic receptor binding all provide mechanisms for general hyperresponsiveness to psychological stressors as a result of maternal deprivation. It is not known whether these same changes result from other maternal deprivation paradigms.

Table 2 Extrahypothalamic effects of neonatal rearing paradigms

Variable	Neonatal paradigm ^a
<i>CRH receptor binding</i>	
Locus ceruleus	HMS180 > HMS0 > HMS15 = AFR
Raphe	HMS180 > HMS0 > HMS15 = AFR
<i>CRF content</i>	
Bed nucleus of the stria terminalis	HMS180 > HMS0 > HMS15 = AFR
Central nucleus of the amygdala	HMS180 > HMS0 > HMS15 = AFR
Hippocampus	HMS180 = HMS0 = HMS15 = AFR
Locus ceruleus	HMS180 = HMS0 = HMS15 = AFR
<i>CRF mRNA</i>	
Bed nucleus of the stria terminalis	HMS180 > HMS0 > HMS15 = AFR
Central nucleus of the amygdala	HMS180 > HMS0 > HMS15 = AFR
Hippocampus	HMS180 = HMS0 = HMS15 = AFR
GR mRNA	
Hippocampus	AFR = HMS15 > HMS0 > HMS180
Prefrontal cortex	AFR = HMS15 > HMS0 > HMS180
<i>α_2-Adrenergic receptor binding</i>	
Locus ceruleus	HMS15 > AFR > HMS0 > HMS180
Nucleus of the solitary tract	HMS15 > AFR > HMS0 > HMS180
<i>GABA_A receptor binding</i>	
Amygdala	HMS180 = HMS0 = HMS15 = AFR
Locus coeruleus	AFR = HMS15 > HMS0 = HMS180
Nucleus of the solitary tract	AFR = HMS15 > HMS0 = HMS180

^aAFR, animal facility-reared control; HMS0, nonhandled; HMS15, handled (brief handling and 15 min per day of maternal separation); HMS180, maternal deprivation (brief handling and 180 min per day of maternal deprivation).

Biological Significance

Accumulating evidence indicates that there are critical developmental windows during which the developing brain is very susceptible to environmental influences. It is postulated that cues related to the environment are transmitted primarily via the primary caregiver, which in most species is the mother. Transmission may be through factors transferred in the milk, aspects of maternal behavior, or both. Maternal-infant interactions and other sensory experiences during these sensitive periods sculpt the final form of the nervous system via multiple mechanisms. The processes of activity-dependent plasticity and hormonal programming act to fine-tune the genetically determined neurocircuitry by altering the strength of connections, changing the morphology of neurons, and altering the expression critical signaling molecules. These changes then lead to robust differences in how that individual decodes and responds to its environment.

Observations of rats exposed to the HMS180 maternal deprivation paradigm suggest a likely cascade initiated by adverse early experience. However, the sequence of this cascade is currently unknown. The initial events lead to impaired function of two primary inhibitory systems: the glucocorticoid-mediated negative feedback system and the GABAergic-CBZ system. Subsequent steps in the cascade involve the dysregulation of CRH and monoaminergic systems.

The relative loss of glucocorticoid tone, as well as of inhibitory GABAergic-CBZ tone in the amygdaloid complex and the locus coeruleus, appears to

disinhibit ascending noradrenergic drive, thus further increasing CRH secretion and gene expression in hypothalamic and extrahypothalamic circuits. Overall, these processes underlie the complex neuroendocrine, behavioral, and cognitive changes observed in response to maternal deprivation in rodents.

Like young rats, both monkey and human babies exhibit elevated glucocorticoid responses during periods of brief maternal separation. Furthermore, early adverse experience in humans also leads to long-term changes in behavior and stress responsiveness. Childhood stressors, including the loss of a parent, neglect, or child abuse, have been associated with an increased vulnerability to mood and anxiety disorders. Models of neonatal maternal deprivation in rats may serve to elucidate the CNS changes occurring in response to adverse early experience in the human and may provide insights into effective prevention and treatment strategies. The mechanisms uncovered by these animal studies may provide a bridge between psychological and psychiatric constructs and their central systems and molecular neuroscience mechanisms.

Sources of Occupational Stress for Medical Professionals
Mediators and Moderators of Occupational Stress
Stress Outcomes for Medical Professionals
Summary

Glossary

<i>Consultant</i>	A specialist medical practitioner providing secondary care, normally in a hospital setting.
<i>General practitioner</i>	A doctor working in primary care in the community; the first point of contact for medical cases of all kinds.
<i>Mediators/moderators</i>	Intervening variables that alter (increase or decrease) the relationship between stressors and strains.
<i>Strains</i>	Physical, psychological, or behavioral outcomes of stressors.
<i>Stressors</i>	External demands or stimuli acting on an individual, perceived as taxing his or her resources.
<i>Transactional models</i>	Models that conceptualize stress as a dynamic interaction between the person and his or her environment.

Sources of Occupational Stress for Medical Professionals

Intrinsic Factors

Although medical work can be routine and repetitive, doctors have high levels of responsibility, necessitating intensive skill use. A wrong decision or diagnosis may put a life at risk or lead to litigation. Doctors must be familiar with a vast area of knowledge and increasingly complex technology, but often act and make decisions in isolation. The corollary of autonomy of decision making is therefore a heavy burden of responsibility and a high degree of accountability for errors. Many aspects of medical work are emotionally stressful, e.g., dealing with death, trauma, suffering, and serious illness and communicating difficult and emotional decisions to patients and relatives. There may be personal moral and ethical dilemmas involved in patient treatment, e.g., in dealing with abortion. Environmental factors may increase personal risk, including exposure to viral infections or contagious diseases such as hepatitis and HIV. There is risk of physical injury from abusive or violent patients, such as in emergency departments, from psychiatrically disturbed patients, or during home visits. Although clinical aspects of medical work can be a source of stress, intrinsic factors have been shown to contribute less to occupational stress than extrinsic or organizational factors. Rigorous training generally equips doctors to deal with clinical issues, facilitating the development of effective coping mechanisms to deal with

clinical responsibilities. However, they may be less well equipped to cope with the hassles of day-to-day management and increased bureaucratization of health care. The repetitive or trivial nature of some patient consultations may be a source of irritation or hassle, and the expectations or demands of patients and their relatives may be perceived as unrealistic.

Workload

Doctors' workload and constant time pressure have been identified as major sources of occupational stress. Several factors may be considered, including overall volume of work, patient list sizes, number of consultations, home visits, unsocial hours and night work, time pressure, and time spent on call. Being on call is described as being in a state of heightened alert, during which it is difficult to relax. Dealing with night calls may result in disturbed sleep, leading to impaired physical and mental functioning. Howie and colleagues assessed the impact of workload in general practitioners (GPs) and found that larger than average list sizes, time pressures (e.g., appointments running late), and more patient-centered attitudes in doctors correlated positively with stress. Faster doctoring and poor time management were associated with less recognition of patients' psychosocial problems and higher rates of prescribing.

Organizational factors such as overbooked and late-running surgeries can lead to shortened consultations and reduced quality of care for patients, whereas improved time management leads to reduced stress for GPs. Agius and co-workers identified demands on time as a major stressor for consultants, including interruptions, meeting deadlines, finding time for research and teaching demands, having so much to do that everything cannot be done well, and conflicts between work and family time as main components. Compared with doctors in hospital settings, general practitioners working in the community may feel constantly visible and on call, leaving less time for self or family. In some countries, the development of GP cooperatives to manage on-call requirements addresses the issue of 24-h commitment to patient care, potentially reducing a major source of occupational stress.

Relationships at Work

Relationships with colleagues are a potential source of stress for doctors. In particular, relationships between medical students and consultants may be a source of stress. Furthermore, the previously competitive style of much medical training is at odds with recent emphasis on the health-care team in general practice. Team working may also introduce interprofessional role conflicts, uncertainties or ambiguities,

and a sense of a diminished role for doctors more accustomed to autocratic or autonomous working styles.

Gender Issues

Male and female doctors have different sources and levels of occupational stress. Despite intakes of women to some medical schools now standing at 50% or higher, women are underrepresented in some specialties (e.g., surgery) and hold fewer consultant grades overall. Patronage in some specialties and the old boys network are still considered to be important parts of the career system discriminating against women. The premise that an increased entry of females to the profession would lead to changes in the structural hierarchy of medical care has not been fulfilled. In India, where sex role segregation is commonplace, medical specialty choice is strongly associated with gender-based stereotypes, with female physicians dealing almost exclusively with women's and children's medical problems.

Role Conflicts: Home-Work Interface

Stress in the home-work interface is common for medical professionals. Stress between work and home is bidirectional and may affect male and female doctors differently depending on the complexity of domestic and occupational roles at different life stages. People-intensive and emotionally demanding medical work may leave the individual feeling drained and uncommunicative with spouse or family, and domestic relationship problems may adversely affect work performance. Female doctors fare less well than male colleagues in maintaining successful marriages, with approximately one-third of female doctors in the United Kingdom remaining single and divorce rates being higher for female than for male doctors.

Mediators and Moderators of Occupational Stress

Transactional psychological models emphasize the importance of individual differences in determining the link between stressors and stress outcomes or strains. Structural characteristics of both the job and the individual medical practitioner influence the stressor-strain relationship.

Structural Factors

The characteristics and type of medical practice (e.g., single-handed, group practice; government funded or profit based) or medical specialty may make them more or less demanding and threatening to doctors' general well-being. Some comparative studies have

identified general practice as one of the most stressful areas of medicine. Anesthetics and psychiatry have also been singled out for being respectively more and less stressful than other specialties. However, evidence regarding the stressfulness of different types of medical specialty is not conclusive. Other studies comparing psychiatric morbidity in doctors in different specialties found no differences among gastroenterologists, surgeons, radiologists, and oncologists or among consultant physicians, surgeons, and radiologists.

Dispositional Factors

The psychological characteristics of individuals who chose a medical career may predispose them to experience work-related psychological distress. Cooper and colleagues suggested that a type A personality predicted reduced mental well-being in GPs, a finding confirmed in other studies, although only a small percentage of variance in strains tends to be explained by type A personality. An internal locus of control has been associated with reduced levels of stress in medical professionals, and neuroticism has been found to correlate highly with occupational stress, emotional exhaustion, depersonalization, and lowered job-related achievement in hospital consultants.

Coping

Doctors possess more resources for coping than most occupational groups due to their length of education and training, status, and financial security. However, few studies have considered coping in doctors. The association between neuroticism and emotion-focused coping strategies used by consultants was linked to a negative appraisal of job stressors by Deary and colleagues. Although maladaptive coping behaviors such as drug or alcohol abuse or work-related strategies such as increased prescribing have been examined, adaptive coping has been studied infrequently. Social support has been identified as an important intervening variable. Increased quality and quantity of social support are associated with a reduction in perceived stress, increased job satisfaction, and improved mental well-being in both male and female doctors, although female doctors utilize a wider range of social support and home- or work-based coping strategies than males.

Stress Outcomes for Medical Professionals

Job Satisfaction

Job dissatisfaction and lowered morale are commonly described outcomes of stress in medical professionals,

with moderate negative correlations between job satisfaction and occupational stress being reported frequently. Job dissatisfaction is associated with poor work performance, mental ill health, and inappropriate prescribing. Female doctors have consistently been shown to report greater job satisfaction than males.

Physical Ill Health

Although medical knowledge is no guarantee of good health, doctors have improved rates of morbidity and mortality in comparison with the general population and other professionals. However, mortality for some causes (e.g., cirrhosis of the liver, road accidents) is substantially higher for doctors than for other comparable professional groups, and concerns have been expressed regarding the tendency of doctors to self-treat or neglect their own health. Because doctors have multiple sources of self-referral, the collection of accurate morbidity data may be more difficult for doctors than for other groups.

Mental Ill Health

Several studies have suggested that doctors have higher rates of mental distress, anxiety, and depression than norms. Because of long working hours, heavy workloads, and the emotional demands of medical practice, younger doctors and those in training may be more vulnerable to psychological distress than older colleagues. However, direct causal links between work stress and mental illness in doctors have not been established firmly. Many studies fail to take into account baseline gender differences in the prevalence of anxiety and depression. Some studies suggest that female doctors suffer from more mental health problems than male doctors or other female professionals, whereas others find no significant differences between female and male doctors or between female doctors and other professional women in stress-related mental distress.

Measures of burnout, encapsulating depersonalization and emotional exhaustion, may be particularly sensitive indicators of strain in medical professionals. One Australian study found that young male GPs were more likely to suffer burnout than young female GPs, suggesting that this may be due to a more empathetic and psychosocial approach to patient care in female doctors. However, other studies have found no gender differences in doctors' burnout. Furthermore, the concept of burnout may overlap a dispositional tendency toward negative affectivity and/or neuroticism, leading to confounding of dependent and independent variables in studies using burnout measures.

Behavioral Outcomes: Alcohol and Drug Use

Doctors generally exhibit a greater prevalence of alcohol and drug abuse than comparable social groups. A main source of drug misuse is via self-prescribing. Psychiatric admissions for alcoholism for male doctors in Scotland were 2.7 times greater than for a comparison group of social class 1 males, with 58% of psychiatric hospitalizations for male doctors in the 45 to 54 age group attributed to alcoholism. GPs in single-handed practices are also overrepresented in hospital admissions for doctors with drug and alcohol problems. General practitioners and some medical specialties, notably anesthetics, have higher rates of alcoholism and drug abuse than others. It has been argued that males in general are more likely to use alcohol as a means of coping with stress than females. This gender difference is reflected in studies of GPs. However, one longitudinal study of junior house officers, albeit in a mixed-gender sample, found no relationship between reported drinking habit and self-reported stress or depression.

Suicide

Suicide rates for doctors in the United States are twice that of the general population and three times that of other professions. Certain medical specialties may have an increased suicide risk, including anesthetics, pharmacy, and psychiatry, although a U.K. study confirmed the excess mortality of doctors from suicide in doctors under 40, but found no difference by medical specialty. Female doctors are also three to four times more likely to commit suicide than females in the general population. An explanation of the elevated suicide rate for doctors is necessarily speculative. The availability of means for suicide (e.g., access to drugs), technical skills, and knowledge ensuring the act is successful may be relevant. Personality characteristics of doctors, including obsessive-compulsive behavior and proneness to depression, may also be important, along with high rates of alcohol and drug abuse and the stress of the doctor's occupational role.

Impact on Patient Care

Although the media image of the overworked, sleep-deprived doctor persists, it has proved methodologically difficult to investigate the impact of stress on doctors' job performance and patient care. Long working hours and sleep deprivation affect work performance in junior hospital doctors, being linked to lowered arousal, attentional deficits, and poor information recall, with fatigued subjects giving less consideration to risks they take. Mechanic's classic

studies of doctors related work frustration to short cuts in work performance, including inadequate examinations and prescribing. Prescribing behavior is one objective indicator of performance, and dysfunctional prescribing is related to job dissatisfaction in GPs. However, reaching agreement as to what constitutes efficient prescribing is difficult.

Summary

A review of studies investigating the extent and impact of occupational stress on doctors indicates that it is pervasive across specialties and cultures. It is therefore crucial for the future well-being of both doctor and patient to identify and manage stress in medical professionals. However, the measurement of stress and strain in this group, as in other occupational groups, has methodological problems. Measurement tools mainly comprise cross-sectional self-report questionnaire surveys and semistructured interview techniques. Response rates vary considerably, questioning representativeness, with some studies being small scale and parochial. The use of a wide range of measures and methods makes comparison among studies, specialties, and cultures difficult. Many studies employing standardized measures of mental ill health, such as the General Health Questionnaire, Maslach Burnout Inventory, and Hospital Anxiety and Depression Scale, report positive correlations between stress and psychological distress, particularly anxiety and depression.

However, few studies have addressed physical or behavioral aspects of the stress response or have considered individual differences as mediators/moderators of stressors/strains for medical professionals. This lack of methodological sophistication is an important omission. For example, where gender is taken into account, females, compared with male doctors, report greater job satisfaction, different behavioral outcomes (e.g., less alcohol and drug use), and a greater use of coping strategies. Similarly, dispositional factors such as neuroticism, which have been clearly associated with strain outcomes such as job dissatisfaction and mental ill health, are often not considered. A shift away from empirical/descriptive stimulus-response models toward more sophisticated transactional conceptualizations in the study of stress in medical professionals is required. This more sophisticated approach has implications for selection, training, and continued professional development of doctors, enabling doctors, managers, and educators to improve specific skills for coping with stress in those medical professionals who need them most. This has relevance for both medical professionals and the patients in their care.

Meditation: Overview and History

Types of Meditation

Theory and Mechanisms

Research Evidence and Clinical Application

Conclusions

Glossary

*Loving
kindness
meditation*
*Mantra
meditation*

A group of guided meditative practices directed toward cultivating compassion toward oneself and others.

Also mantram. A widely practiced form of concentrative meditation in which a word or short phrase is repeated, usually silently, to oneself. In traditional usage, the mantra carries with it spiritual significance. Om, referring to the presence of the absolute within, is one of the most familiar mantras.

Shamatha

Sustained quieting or calming of the mind; meditative practices that are directed toward doing so.

Vedanta

Refers to the Vedas, part of the foundation of Hinduism, as interpreted in the mid-1800s by the Indian mystic Sri Ramakrishna, who promulgated an ecumenical world view of religion and meditative practice. The Vedanta Society was founded by Swami Vivekenanda, his chief disciple, in the United States in 1893, and maintains a number of centers today.

*Vipassana
Yoga*

Insight or mindfulness meditation.

To yoke or link the mind/spirit and body. Meditation is one traditional means by which this occurs. Hatha yoga, referring to practice of physical postures, is one branch of the traditional Yogic system.

Meditation: Overview and History

The therapeutic use of meditation may be unique within contemporary psychology, as it draws explicitly on non-Western traditions to inform both the

practice and the conceptual understanding of meditation effects. Awareness of Hindu and Buddhist meditative and yogic traditions entered Europe and the United States from India, Japan, and China beginning in the 1800s, influencing the Theosophist movement, which adopted the term meditation to refer to a wide range of related practices. Interest was further sparked by the 1883 Parliament of the World's Religions; some Zen and Hindu-based practices in the United States can still be traced directly to this conference, through the influential writings of Alan Watts on Zen Buddhism and the Vedanta Society. The first documented secular adaptation of meditative practices to therapeutic use was Johannes Schultz's development of autogenic training in 1932, which used slow-paced breathing and mindful awareness of physical sensations to facilitate deep relaxation experiences. The writings of D. T. Suzuki on Zen practice stimulated interest in meditation in the 1950s by psychodynamic therapists, particularly Fromm and Horney, and fueled openness to more secular forms of meditation, such as transcendental meditation, a decade later. There is increasing recognition of similarities in meditative and contemplative practices across world religious traditions, including Christianity, Judaism, and Islam, in both process and purpose.

Types of Meditation

Meditative techniques are generally classified into two types: concentrative meditation and mindfulness meditation. Concentrative techniques involve sustained attentional focus on a specific object, such as a mantra (a repeated sound or word), with a goal of complete absorption, suspension of everyday preoccupations, and calming the mind, whereas mindfulness meditation cultivates sustained attentive awareness to whatever may emerge into conscious experience, without reaction or analysis. In addition, guided meditation, in which attention is directed to a particular type of experience (i.e., an emotion, such as anxiety, a physical feeling, such as pain, or a type of thought), can be considered a third category that may have particular value in regard to therapeutic effects. Tibetan Buddhist practices are particularly rich in complex guided meditations. However, these distinctions are a matter of degree: awareness cannot occur without sustained attention, and sustained attention or concentration cultivates awareness. Most traditional meditative approaches incorporate aspects of both concentrative and mindfulness practice. Focused concentration may be more powerful in inducing trancelike states. Yet, as active thinking and feeling processes are quieted, similar states of transcendent experience may be achieved through a

wide range of practices, as evident from phenomenological descriptions of meditative experience across traditions.

Concentrative Meditation

A wide variety of traditional concentrative techniques exist, but the most common involve focus on the breath (e.g., in Buddhist Shamatha meditation), focus on a word or phrase (e.g., the mantra), or visualization of an object (e.g., as in Tibetan mandala meditation). Transcendental meditation (TM), the most widely researched version of Hindu mantra or concentrative meditation that has been used therapeutically, was created in the 1960s for teaching in the West by the Maharishi Mahesh Yogi; other influential Hindu-based meditation groups in the United States include the Vedanta Society, founded in 1893, and the Himalayan Society, founded by Swami Rama in 1971. Recently, Catholic Centering Prayer, as being revived from early Christian practices by Father Thomas Keating, has garnered increasing attention, and is strikingly similar in many respects to other mantra meditations. In TM, the mantra is generally a Sanskrit word or phrase assigned by a TM teacher and is intended to have a spiritual, although not religious, meaning. TM practice involves sitting quietly in a relaxed posture for 20 min twice a day, with closed eyes. The mantra is repeated silently to oneself, with attention returned to it as thoughts wander to other experiences. Unlike some concentrative techniques, TM practitioners are instructed that attention is to be directed in an effortless manner.

Benson further secularized this practice in the 1970s for research and clinical applications, coining the term the relaxation response, and suggesting that practitioners use the word "one" as a mantra, but other words or phrases, whether of a secular or spiritual meaning, may be used. Eknath Easwaran, an Indian scholar and meditation teacher based in California, developed a transcultural approach that uses both mantra-based meditation and longer memorized textual passages; although he is deceased, his work is increasingly being utilized in treatment programs. These concentrative approaches have all been integrated into more comprehensive treatment programs.

Mindfulness Meditation

Mindfulness techniques have been introduced primarily through Vipassana or insight meditation drawn primarily from southeast Asian Theravadan practices (Thai, Vietnamese, and Burmese), Japanese Zen *shikantaza* ("just sitting"), and visualization and other techniques from the very rich Tibetan traditions.

Body-focused awareness is also cultivated in a number of traditions; the word yoga means to connect (or yoke) the mind and body. Influential venues by which these traditions entered the United States were a number of Zen monasteries founded beginning in the 1960s; the Naropa Institute in Boulder, CO, founded in 1974 by the Tibetan monk Chogyam Trungpa Rinpoche; and the Insight Meditation Society, founded in 1975 by Jack Kornfield, a psychologist who studied Buddhism in Thailand, and his associate Sharon Salzberg, among others. The prolific writings of Thich Nhat Hanh, a Vietnamese Zen monk, have been particularly influential in regard to loving kindness meditation and walking meditation. A contemporary Asian mindfulness meditation retreat program, developed by S. N. Goenka in Burma and India, uses a traditional 10-day intensive practice format and has been explored for use in prison populations and with drug addicts in both India and the United States.

The Mindfulness-Based Stress Reduction (MBSR) program, developed by Jon Kabat-Zinn in 1981 at the University of Massachusetts Medical Center, is the most widely used and researched therapeutic approach drawing on mindfulness meditation techniques; it was influenced by both Vipassana and Korean Zen traditions, in combination with yoga and body-focused meditation. The MBSR program uses the breath as an attentional focus but also emphasizes cultivating detached, nonjudgmental awareness of whatever arises into consciousness. Practice is generally a single sitting meditation session per day of 40–45 min, though this may be shortened as appropriate for use with children or other groups. Maintaining an erect posture is emphasized, consistent with a goal of staying alert. Engaging a trancelike state is avoided. Variations on the MBSR program include Mindfulness-Based Cognitive Therapy (MBCT), developed by Teasdale, Segal, and Williams, and Mindfulness-Based Eating Awareness Therapy (MB-EAT), developed by Kristeller. MBCT incorporates cognitive therapy techniques designed to address depressive thinking; MB-EAT incorporates cognitive and self-regulation approaches to management of compulsive overeating and obesity. Linehan's Dialectical Behavior Therapy incorporates brief mindfulness meditation practices into an intensive group treatment program for borderline personality disorder.

Theory and Mechanisms

Meditation involves the intentional cultivation of moment-to-moment, nonjudgmental awareness of one's present experience, whether narrowly or more

broadly focused. The goal of these practices is to develop an ability to bring stable and nonreactive awareness to one's internal (cognitive-affective-sensory) and external (social-environmental) experiences and thereby heighten the capacity to bring conscious control to responses and reactions. Within Buddhist psychology, meditation is identified as the most important means to bringing forth skillful action, speech, livelihood, effort, understanding, and thought. It is through meditation that higher wisdom in all areas of life is sought and achieved. These dimensions map fairly well onto the range of meditation effects that have been explored scientifically, including physical relaxation, emotional well-being, behavioral regulation, improvement in relation to self, growth in compassion toward others, and spiritual enlightenment or a sense of transcendence.

The psychology of meditation practice must therefore consider how it is that a group of relatively simple attentional and cognitive practices may bring about this range of effects. The means through which this is thought to occur within Buddhist psychology is again compatible with contemporary learning theory. Within contemporary Buddhist psychology, distress is viewed as a function of conditioning leading to cravings and aversions, which create *dukkha* (suffering or stress) and are incompatible with higher or wiser levels of functioning. The traditional goal of meditation practice is release from craving or conditioning. This is strikingly parallel to learning models of stress, as expressed in anxiety disorders, addictive behaviors, and depressed mood or cognitions.

Several fundamental mechanisms are likely to be involved in early and intermediate stages of practice. Advanced stages may engage more complex processes related to altered states of consciousness that are somewhat distinct, or that, as Austin posits, may be on a continuum with more fundamental shifts in neuropsychological functioning. First, focusing attention on a neutral repetitive object, whether it be the breath, a mantra, or a repeated chant, disengages attention from other targets that may be stress related. This process may produce stress-reducing effects similar to those of any distracter but is different in that the mind is not then caught up in an alternative source of attention. It is not uncommon with initial practice for individuals to note how profoundly relaxing they find the experience. The next step is cultivation of the ability to rest the attention on a neutral stimulus, such as the breath or the mantra, in a more sustained manner. This is intended to generalize to increased ability to sustain attention on other objects (sometimes referred to as bare attention). Linked to this process, and heightened in mindfulness meditation, is observing the occurrence of

patterns of habitual or conditioned responding, a type of reflective self-monitoring. Initial practice often brings awareness of the chattering mind, the undisciplined pattern of racing thoughts. Sustained attention then leads to an active disengagement of usual reactivity, analysis, or letting the attention move unbidden to the next association, emotion, or response. Simply observing experiences such as pain sensations, anxiety, or cravings, without reacting, may share similarities with systematic desensitization, in that repeated exposure, without either withdrawal or reinforcement, interrupts the feedback loop of the conditioning process. Therapeutic value may be amplified by guided meditations that utilize specific objects as targets for mindfulness practice, such as the experience of pain, fear, anxiety, eating, or compassion. Another value in maintaining sustained attention is similar to what Marlatt describes in the addiction literature as urge surfing: coming to the realization that by observing an experience or impulse in a sustained way, one discovers that these experiences are not constant, but rise and then fall away.

One hallmark of highly conditioned reactive responses is that they occur so quickly or are so powerful that alternatives cannot emerge or are not experienced as sustainable. As automatic reactive patterns are disengaged, the potential emerges for alternative choices that may have been lying dormant. Meditators often report that they observe the

alternative choices that arise as fresh and in some way unexpected, yet emerging from their own capabilities, rather than being directed or prescribed from the outside. Even at early stages of practice, individuals will note that it becomes easier to introduce a moment of silence or space into daily choices and that making a healthier decision no longer feels like as much of a struggle as it once did.

Figure 1 illustrates several of these steps in regard to mindfulness practice. Awareness is heightened in regard to stress responses (1a), such as anger or overeating (Y), the trigger (X) for that response, and the connections between the trigger and the response (1b). Resting attention with this awareness then acts to disengage or disconnect the trigger from the response (2a) and the feedback/reinforcement value (2b) from the response to the trigger. When these links are disconnected, access to alternative choices (A, B, or C) becomes available (3); with further practice, a novel or wiser response (W) may emerge (4).

Cultivating bare attention also appears to disengage a sense of self-identification with the experience, i.e., being able to say “I feel the pain, but I am not my pain.” This disidentification of self from experience is considered to play a primary mediational role within some meditative traditions; one counterpart in contemporary psychology is the recognition that the constructed self, along with critical self-judgment, is often central to distress and psychopathology. This

Figure 1 Illustration of several steps in regard to mindfulness practice. Awareness is heightened in regard to stress responses (1a), such as anger or overeating (Y), the trigger (X) for that response, and the connections between the trigger and the response (1b). Resting attention with this awareness then acts to disengage or disconnect the trigger from the response (2a) and the feedback/reinforcement value (2b) from the response to the trigger. When these links are disconnected, access to alternative choices (A, B, or C) becomes available (3); with further practice, a novel or wiser response (W) may emerge (4).

disidentification may be accompanied by a sense of liberation, a release from operating on automatic, whether from the usual chatter of the conscious mind or from more challenging patterns, such as anger, drinking, or compulsive eating.

Spiritual growth as a functional result of meditation practice may also occur due to disengagement of more immediate survival needs. Spiritual engagement is being increasingly recognized as a potent protective factor when individuals are under high stress conditions. While understanding the neuropsychological processes underlying spiritual or mystical experience is at an exploratory stage, meditative traditions universally aim to cultivate such experiences; disengagement of ordinary cognitive processing appears to be a necessary, if not sufficient, foundation for engaging spiritual or mystical experience.

Research Evidence and Clinical Application

Background

Contemporary research on meditation effects is generally dated from early studies in the 1950s on physiological effects in Indian yogis and Japanese Zen masters. Research on the clinical application of meditation is usually considered to date from the early work with TM or from the publication of Benson's *The Relaxation Response* in 1973. Murphy and Donovan's annotated 1996 bibliography summarizes more than 1000 studies on meditation.

It is useful to organize research evidence, both experimental and clinical, around the six domains noted earlier: cognitive/attentional, physiological/health, emotional, behavioral, relation to self/others, and spiritual. Clearly, these domains intersect and overlap, but such an approach helps in considering underlying mechanisms. For example, traditional perspectives on meditation practice have tended to focus on self-transformation and spiritual growth, yet it is apparent that substantial health and emotional effects in novice meditators can be obtained independently of such changes. The level of experience of research participants may vary from thousands of hours of meditation experience to individuals just being introduced to a given practice. Methodological quality varies greatly, and until recently, few studies met criteria for well-controlled randomized clinical trial research. Yet Grossman's meta-analytic review of 20 well-designed MBSR intervention trials found substantial effect size estimations of approximately 0.50, across various samples and problem areas. Neuroimaging techniques may prove particularly

valuable in identifying possible underlying processes, given the inherent introspective nature of the processes involved. Somewhat surprisingly, there are very few studies comparing concentrative and mindfulness meditation (or other meditation) techniques.

Individual differences have also been of interest; an early model suggested that individuals higher on cognitive anxiety might respond better to meditation techniques than to more body-centered relaxation interventions. However, several attempts to confirm this model either failed to do so or found that the variance accounted for was very small. Clinically, some individuals who drop out of meditation practice report that the experience is boring; conversely, others have difficulty with racing thoughts that they are unable to quiet. Beginning with shorter time periods, use of a mantra, or other techniques, such as breath counting, can help with these problems. Although the basics of meditation practice appear relatively simple, it is generally strongly emphasized that one should have a meaningful personal practice before using meditation therapeutically with others.

Efforts to use self-reporting to measure mindfulness have greatly accelerated in the past few years. Baer's factor analytic research has identified five facets of mindfulness that can be measured in both meditators and nonmeditators, including attending to experience, nonjudging, nonreactivity to inner experience, describing experience in words, and acting with awareness; this research is still in the formative stage. The revival of interest in spirituality as a psychological construct is also contributing to measurement of this aspect of meditation practice.

Cognitive and Attentional Effects

Most of the research on attentional and cognitive effects of meditation has investigated concentrative and TM approaches. Although evidence is not entirely consistent, there appears to be an improvement in field independence, reaction time, sustained attention, and ability to detect detail in rapidly presented material. Additional research is needed to investigate the role of meditation in affecting the cognitive processes hypothesized to mediate other effects.

To date, clinical application within this domain has been limited, but preliminary evidence suggests that there is value in using mindfulness meditation in treating attention-deficit disorder. Clinically, one of the notable cognitive effects is an experience of inner silence, of quieting the mind to the point that inner self-talk is not experienced. Beginning meditators often express frustration that they cannot silence their thoughts, not understanding that such silence is the result of practice and of the ability to disengage,

and is difficult, if not impossible, to force. The occurrence of such silence may be an important marker of a shift in neuropsychological functioning and deserves further investigation.

Physiological and Health Effects

Within the domain of physiological effects, the most robust research findings are related to a shift in balance of less sympathetic to greater parasympathetic autonomic nervous system function, accompanied by feelings of relaxation, decreases in blood pressure, and lowered levels of stress hormones. This shift is essentially what Benson has referred to as the relaxation response. There are also primary physiological effects due to slowed breathing; respiration rates of two to four cycles per minute have been shown in separate studies by Benson and by Lehrer to lead to marked physiological changes, including increases in body temperature, in Tibetan and Rinzai Zen monks, two traditions in which such slow-paced breathing is cultivated. Central nervous system effects have primarily focused on changes in alpha and theta rhythm dominance during practice. The increase in theta activity is sometimes interpreted as indicating that meditators are simply falling asleep; while this may occur, a pattern of sustained (nondescending) theta suggests a distinct state of consciousness. More recent work is documenting increased synchronization of activity across regions of the brain and heightened gamma activity in advanced meditators.

Impact on health through lowering of cortisol levels, lowering of blood pressure in both adults and adolescents, and improved management of pain and immune functioning deserve further exploration. Chronic pain patients have been shown to respond remarkably well to the rigorous combination of sitting meditation, gentle hatha yoga, and body awareness practices, with decreases in pain experience and increases in pain tolerance. A randomized clinical trial documented improvement in fibromyalgia patients, but these effects were not replicated using an attentional-support control comparison group. Evidence is limited regarding improvement in immune functioning in cancer patients enrolled in an MBSR program, but research by Carlson and colleagues found improvement in several indicators of immune response in breast and prostate cancer patients, including interleukin (IL)-4. They also found improved diurnal profiles in salivary cortisol, which is associated with survival time. A notable use of guided mindfulness meditation practice has been in conjunction with standard treatment of psoriasis, leading to markedly faster clearing rates of this chronic skin disease.

Emotional Effects

Meditation can be considered one of the few tools for systematic cultivation of emotional equanimity, an advanced level of stress and affect tolerance. Improvement in emotional well-being has been documented in multiple studies with both concentrative and mindfulness meditation practice, and in both novice and more advanced meditators. Reduced anxiety, anger, and depression and heightened experience of well-being have been documented in a number of studies involving both clinical and non-clinical populations. The MBSR program has been used successfully to treat individuals with diagnosed anxiety disorders, producing long-term effects for those with panic attacks and agoraphobia. There is a growing literature showing the value of MBCT in preventing relapse in individuals with three or more previous episodes of major depressive illness. The MBCT program integrates cognitive-behavioral components into the structure of the MBSR program, in addition to using guided meditations in regard to depressive thoughts.

Meditation practice, however, may not uniformly result in a positive emotional experience. Because one of the mechanisms involved is interrupting dominant conditioned responses, emotionally painful experiences or even flooding with uncovered memories of traumatic events may emerge when constructed mechanisms for suppression are disengaged. In the general population, the incidence of these experiences is very low, but this may increase substantially in psychiatric populations, requiring tailoring of the meditation practice and guided support from the therapist. The value of mindfulness techniques, including brief meditation, with borderline personality disorder is now well supported in research on Linehan's Dialectic Behavior Therapy. There is a growing clinical literature by such individuals as Epstein, Rubin, and Germer and colleagues on the integration of meditation practice into psychodynamic psychotherapy.

Meditation and Behavior

Improved behavioral regulation may be the result of several factors: the interruption of chains of behavioral reactions as awareness is cultivated, improved emotional regulation, increasing receptivity to behavioral/lifestyle recommendations, or learning to tolerate and ride out waves of craving, rather than responding impulsively. Much of the research literature focused on behavior change has investigated the effects of TM on reductions of drug, smoking, and alcohol intake, with claims made of substantial

improvement in long-term abstinence, depending on the amount and duration of practice. While suggestive, randomized clinical trials are needed to investigate the effects of both concentrative and mindfulness-based meditative interventions. The MB-EAT program has preliminary support of effectiveness in treating binge eating disorder, as does Dialectical Behavior Therapy.

Relation to Self and Others

Cultivating compassion toward oneself and toward others is central to Buddhism; cultivating the capacity to disengage from self-preoccupation is a central goal of meditative practice in all contemplative traditions. Overidentification of self with either positive or negative experience may contribute to stress and interfere with self-growth. Research evidence has supported the development of self-acceptance when under stress in more advanced meditators in both concentrative and mindfulness traditions. Such self-acceptance may come through disengaging from usual preoccupations and cultivation of insight, and may be heightened through use of loving kindness meditations. Increases in both self-growth and empathy have been observed in couples, therapists, and other health professionals enrolled in relatively brief (4- to 8-week) meditation programs.

Profound transformative experiences have been documented in incarcerated individuals enrolled in Goenka's week-long intensive meditation retreats in prisons in India and the United States. Evidence is accruing that advanced meditators practicing within Tibetan traditions that involve extensive guided meditation on cultivation of compassion exhibit strikingly higher left prefrontal cortex activity that underlies positive emotion. It is unclear whether such effects emerge inherently from intensive practice, are mediated through attentional and cognitive disengagement of self-preoccupation, or require domain-specific guided meditations, such as loving kindness practices.

Spiritual Well-Being

Recent research on spiritual well-being in medical populations suggests that it is a powerful factor in overall adjustment, despite high levels of stressors. Cultivation of spiritual growth and well-being is fundamental to virtually all meditative traditions, but different emphasis is placed on the centrality of achieving spiritual or transcendent experience across different traditions; furthermore, the degree to which this is viewed as a secular goal (as within TM or some schools of Buddhism and Hinduism) or as an inherently religious goal (as within Judeo-Christian

contemplative traditions) varies substantially. Research with novice meditators using both concentrative and mindfulness practices is beginning to document modest shifts in spiritual well-being, using psychometrically sound self-report measures.

Concentrative meditative practices are recognized to more readily cultivate trance states even in novice meditators, and induction of mystical experience is being examined in neuroimaging studies in highly experienced meditators. D'Aquili and Newberg's research on advanced meditators has garnered substantial attention in positing a neurophysiological basis for suspending a sense of the self and engaging the experience of union with a higher being.

Conclusions

Meditation practice, as it is currently understood, engages mechanisms that promote effects far broader than basic physical or emotional relaxation. To summarize, meditation can affect the stress response in a number of ways: first, it serves as a neutral distractor; second, mindfulness meditation teaches the capacity for self-observation of patterns of experience; third, the capacity to sustain awareness without responding or reacting is heightened. With yet more practice, conditioned reactions and responses to inner experience gradually weaken; finally, in the course of this uncoupling, meditation appears to facilitate the emergence of more integrative responses. Specific therapeutic goals may be facilitated by directing meditative awareness toward the target of concern, such as anxiety symptoms or pain management. By understanding meditation practice as engaging these processes, it becomes clearer how a range of therapeutic effects may occur as a function of a relatively simple set of practices, much as other principles, such as cognitive restructuring, behavioral techniques, or insight-oriented psychotherapies, are applied to a wide range of therapeutic issues.

Both concentrative and mindfulness approaches have developed and gained acceptance over the past 30 years as valuable components of treatment programs for a wide range of disorders and presenting issues. The literature on meditation, as it can be incorporated into therapeutic modalities, continues to expand. Research also continues to explore underlying mechanisms, in ways that may inform a greater understanding of self-regulatory processes in general. As the theoretical framework for understanding meditation psychotherapeutically evolves, it becomes more evident that meditation cannot be dismissed either as an esoteric spiritual/religious practice or as only one of many relatively simple relaxation techniques.

Glossary

<i>Corticosteroid-binding globulin (CBG or transcortin)</i>	A plasma protein that specifically binds corticosteroids.
<i>Corticotropin releasing factor (CRF)</i>	A 41 amino acid residue hypothalamic peptide that mediates the neural control of pituitary adrenocorticotropin secretion.
<i>Dexamethasone</i>	A synthetic glucocorticoid.
<i>EC₅₀</i>	The dose of a hormone or drug necessary to produce 50% of the maximal response.
<i>GABA</i>	γ -Aminobutyric acid, an inhibitory neurotransmitter.
<i>GABA_A receptor</i>	A membrane protein complex that forms an agonist-gated chloride ion channel and mediates fast inhibitory synaptic transmission.
<i>K_D</i>	Equilibrium dissociation constant. The concentration of ligand at which 50% of the receptors are occupied.
<i>Nongenomic</i>	A mechanism of steroid hormone action that does not initially involve modulation of gene transcription.
<i>RU38486 (Mifepristone)</i>	A synthetic progesterone receptor antagonist that binds with high affinity to the cytosolic glucocorticoid receptor.
<i>TBPS (t-Butylbicyclophosphorothionate)</i>	A competitor for binding of GABA to the GABA _A receptor.
<i>Triamcinolone acetate</i>	A synthetic glucocorticoid.

Glucocorticoid Receptors

Cellular and organismal responses to glucocorticoid hormones are complex and integrative, involving immediate, short-term, and long-term components. Target cell responses to glucocorticoids are initiated by two main mechanisms. In the classical, genomic mechanism, glucocorticoids interact with intracellular receptors, which act as ligand-gated transcription factors. The ligand–receptor complex then regulates the transcription of specific genes by interaction with hormone response elements and/or AP-1 transcriptional regulatory sites. This mechanism produces responses that are usually apparent in hours or days.

In the other, nongenomic, mechanism, glucocorticoids initiate immediate or very short latency responses in target cells. These short latencies preclude the genomic mechanism of transcriptional activation/inhibition and altered translation, although genomic responses may follow rapid responses. It is believed that these responses are mediated by glucocorticoid receptors that are integral to or associated with target cell plasma membranes. Membrane-associated glucocorticoid receptors have not been cloned, but several membrane-associated glucocorticoid-binding proteins have been purified, and there are numerous reports of nongenomic physiological and behavioral responses to the hormones (Table 1). Receptor binding studies have characterized glucocorticoid binding to plasma membranes in various tissues from several species (Table 2), and some of the cellular signaling mechanisms activated by the hormones have been elucidated. Multiple classes of glucocorticoid-binding sites have been revealed in plasma membranes: (1) membrane-associated glucocorticoid receptors distinct from intracellular glucocorticoid receptors, (2) membrane-associated forms of intracellular glucocorticoid receptors, (3) membrane receptors for corticosteroid-binding globulins (CBG), (4) membrane glucocorticoid-transporting proteins, and (5) other membrane proteins that also bind glucocorticoids. These proteins have been distinguished pharmacologically, based on binding specificity profiles for various natural and synthetic ligands, and immunologically, based on cross-reactivity with antibodies for intracellular glucocorticoid receptors. This article reviews the membrane glucocorticoid receptors and describes what is known of the mechanisms by which they initiate rapid cellular/organismal responses.

Glucocorticoid Receptors in Liver

The liver, a major target organ for glucocorticoid hormones during stress, shows both immediate and long latency physiological responses to glucocorticoid hormones and has both cytosolic and membrane glucocorticoid receptors. Radioligand binding and photo-affinity labeling reveal high-affinity ($K_D = 7\text{--}12\text{ nM}$) and low-affinity ($K_D = 90\text{--}344\text{ nM}$) membrane-binding sites for both dexamethasone and cortisol (see Table 2) in rat and chicken hepatocytes. The sites appear to be integral membrane proteins, as they can be extracted by detergent, but not by high salt. The sites for the two glucocorticoids also appear to be distinct from each other. Low-affinity dexamethasone binding is attributed to a 45-kDa protein, whereas two membrane proteins, 52 and 57 kDa, are responsible for cortisol binding. Glucocorticoid-binding sites have also been demonstrated visually in rat hepatocyte membranes. Gold-conjugated corticosterone-bovine serum albumin (BSA) specifically labels the apical, but not the lateral, membranes of hepatocytes (see Table 2).

During stress, glucose stores in the liver are mobilized rapidly by the activation of glycogen-degrading enzymes in the hepatocytes. This effect is largely due to the actions of catecholamines, but glucocorticoids also play a role. Corticosterone, dexamethasone, and cortisol increase the activity of glycogen phosphorylase, a glucose-liberating enzyme, in rat and chicken hepatocytes within 10 min of administration (see Table 1). Glucocorticoids act in this case via a Ca^{2+} -mediated signaling process, as the effect is diminished in Ca^{2+} -depleted medium. Other rapid effects of glucocorticoids in hepatocytes include increases in the phosphorylation of histone and nonhistone proteins and general activation of translational machinery, including increased synthesis of intracellular glucocorticoid receptors (see Table 1). These rapid effects may facilitate long-term, genomic responses to glucocorticoids.

Glucocorticoid Receptors in Lymphocytes

The immune system is another major target of glucocorticoid hormones. Membrane-mediated effects of glucocorticoids and membrane-associated forms of the intracellular glucocorticoid receptor have been demonstrated in various lymphocytes. In rat mast cells and basophils, cortisol inhibits the antigen-induced release of histamine and attenuates the antigen-induced release of Ca^{2+} from intracellular stores (see Table 1). This effect may be related to the potent antiallergic actions of glucocorticoids.

Studies with antibodies have demonstrated that a population of human lymphoma cells possesses a

membrane-associated form of the intracellular glucocorticoid receptor (see Table 2). Cells that possess this form of the receptor are particularly sensitive to glucocorticoid-induced cytolysis.

Glucocorticoid Receptors in Adrenal Gland

Both the adrenal cortex and the adrenal medulla are targets of rapid glucocorticoid hormone action. Rapid effects in both areas appear to be related to the feedback regulation of adrenal hormone release. Corticosterone decreases the secretion of adrenal steroids from frog interrenal gland by 45–80%. This effect is not mimicked by dexamethasone and is not blocked by the specific glucocorticoid receptor antagonist RU43044 (see Table 1), indicating that this ultra-short feedback regulation of adrenal steroid secretion is mediated by another type of glucocorticoid receptor.

A membrane glucocorticoid-binding site in bovine adrenal cortex has high affinity ($K_D = 77\text{ nM}$) for corticosterone and very low affinity ($\text{IC}_{50} = 25\text{--}50\text{ }\mu\text{M}$) for dexamethasone, triamcinolone, and cortisol (see Table 2).

Chromaffin cells of the adrenal medulla secrete catecholamines in response to a variety of neurotransmitters, including acetylcholine. These cells are exposed to very high concentrations of glucocorticoids in venous blood from the adrenal cortex. At high concentrations (up to $10\text{ }\mu\text{M}$), glucocorticoids modulate the responses of adrenal chromaffin cells to acetylcholine and to K^{+} -induced depolarization rapidly (see Table 1). Dexamethasone immediately diminishes the acetylcholine-induced current when applied extracellularly to dispersed guinea pig chromaffin cells, but has no effect when applied intracellularly. In PC12 cells from rat medullary tumors, corticosterone and corticosterone-BSA inhibit depolarization-induced intracellular Ca^{2+} release by a mechanism that involves G-protein-mediated calcium signaling.

Glucocorticoid Receptors in Pituitary

Several hypothalamic peptide hormones can cause cells of the anterior pituitary to release adrenocorticotrophic hormone (ACTH), which in turn stimulates the release of glucocorticoid hormones from the adrenal cortex. Glucocorticoids regulate pituitary production/secretion of ACTH in a complex system of feedback inhibition. This inhibition occurs on rapid (seconds to minutes), delayed intermediate (10–15 min to hours), and delayed slow (hours to days) time courses. Rapid feedback inhibition of pituitary ACTH secretion by

Table 1 Selected membrane-mediated effects of glucocorticoids

Hormone	Effect	Tissue	Dose (EC_{50}) ^a	Organism	Reference
Liver					
Corticosterone/ dexamethasone	↑ glycogen phosphorylase activity	Hepatocytes	1–10 μ M B; 10–1000 nM Dex	Rat	Gomez-Munoz et al. (1989). <i>Biochem. J.</i> 262 , 417–423
Cortisol	↑ glycogen phosphorylase activity	Hepatocytes		Chicken	Sancho et al. (1986). <i>Biochim. Biophys. Acta</i> 88 , 249–255
Adrenal					
Corticosterone	↓ depolarization-induced calcium release	PC12 cells	100 nM–10 μ M	Human	Lou and Chen (1998). <i>Biochem. Biophys. Res. Commun.</i> 244 , 403–407
Dexamethasone	↓ acetylcholine-induced current	Chromaffin cells	10 μ M	Guinea pig	Inoue and Kuriyama (1989). <i>Am. J. Physiol.</i> 257 , C906–C912
Corticosterone	↓ steroid release	Interrenal tissue	10 μ g/ml	Frog	Netchitailo et al. (1991). <i>J. Mol. Endocrinol.</i> 6 , 249–255
Intestine					
Cortisol	↑/↓ GABA-induced contractility	Ileum	1–10 pM (↑); 10–1000 nM (↓)	Guinea pig	Ong et al. (1987). <i>Neurosci. Lett.</i> 82 , 101–106.
Endometrium

^aIndicates that the glucocorticoid-binding protein has been purified.

glucocorticoids is thought to be mediated by membrane receptors. The stimulation of ACTH release by CRF, oxytocin, vasopressin, and insulin is diminished rapidly by glucocorticoids, including corticosterone, cortisol, and dexamethasone (see Table 1). These effects are not completely understood, but appear to involve the attenuation of secretagogue-induced increases in second messenger accumulation. Some fast feedback effects, with latencies of 15–20 min, have been attributed to rapid protein synthesis.

Glucocorticoid-binding sites have been characterized in plasma membranes from rat and mouse pituitary cells (see Table 2). The rat membrane receptor has high affinity ($K_D = 3.2$ nM) for corticosterone and does not bind dexamethasone. Mouse pituitary tumor (AtT-20) cell membranes specifically bind corticosterone, but not dexamethasone or triamcinolone. This binding site appears to be a glycoprotein, as treatment of cells with proteases abolishes glucocorticoid binding and treatment with neuraminidase enhances binding.

The release of other pituitary hormones can also be modulated by glucocorticoids. In pituitaries of the teleost fish tilapia, cortisol inhibits the release of prolactin rapidly, apparently via the membrane-mediated modulation of Ca^{2+} and cAMP levels (see Table 1).

Glucocorticoid Receptors in Brain

Stress effects on neuronal activity and animal behavior are widely varied, stressor specific, and dependent

on the endocrine/sensory history of the organism. Rapid glucocorticoid actions on neurophysiology and behavior show the same variability. In the brain, glucocorticoids can modulate both spontaneous and evoked neuronal activity rapidly. The direction of this modulation (increase or decrease) depends on the identity of the target neuron and is often context dependent. In the rat hypothalamus, for instance, corticosterone increases the activity of oxytocin-secreting neurons, but is mainly inhibitory to vasopressin neurons and neurons projecting to the median eminence (see Table 1). In the newt, corticosterone inhibits the responses of naive medullary reticular neurons to sensory stimuli, but it potentiates sensory responses of the same neurons when they have been previously exposed to vasotocin (see Table 1). Glucocorticoid-induced increases in sparrow perch-hopping behavior are dependent on photoperiod.

The best correlations between glucocorticoid-binding characteristics of membrane receptors and doses of glucocorticoids necessary for rapid physiological/behavioral effects have been demonstrated in the brains of rats and newts. In rat brain synaptosomes, corticosterone causes an increased uptake of Ca^{2+} and tryptophan (see Table 1). The EC_{50} for this effect (130 nM) is almost identical to the K_D (120 nM) determined for glucocorticoid binding to synaptic plasma membranes from the rat brain. In newts, corticosterone causes a rapid inhibition of male courtship behavior (see Table 1). This effect has an EC_{50} of 0.6 nM and is not mimicked by dexamethasone.

The K_D for corticosterone binding to newt synaptic plasma membranes is 0.5 nM, and dexamethasone does not compete with corticosterone for this binding site.

Other effects of glucocorticoids in the brain include rapid modulation of neuropeptide release by hypothalamic neurons, modulation of spontaneous neuronal activity in various brain regions, and modulation of neuronal responses to sensory stimuli (see [Table 1](#)). It is likely that these rapid neuronal responses to glucocorticoids mediate rapid changes in behavior during stress.

Glucocorticoid Transport Proteins

There is still debate over the mechanisms by which glucocorticoid hormones cross plasma membranes. Certain membrane glucocorticoid-binding proteins also transport the steroids across the plasma membrane. One major membrane steroid transporter, P-glycoprotein, binds corticosterone, cortisol, and dexamethasone and transports them out of cells. This protein is expressed at high levels in epithelia of adrenal cortex, kidney proximal tubule, biliary hepatocytes, brain capillaries, small intestine, and colon.

Rat liver plasma membranes possess a bidirectional glucocorticoid transporter that is specific for corticosterone and cortisol. Immunochemical methods demonstrate that this binding site is distinct from P-glycoprotein. Specific transmembrane transport of glucocorticoids has also been demonstrated in membrane vesicles from pituitary and placenta.

Corticosteroid-Binding Globulins

Of the pool of glucocorticoid hormones circulating in the blood, a substantial fraction occurs bound to plasma proteins. Adrenal steroids (cortisol, corticosterone, and deoxycorticosterone) bind specifically and with high affinity to corticosteroid-binding globulin (or transcortin). While its functions are still unclear, CBG does interact specifically with a plasma membrane receptor. Specific, high-affinity CBG receptors have been purified from plasma membranes of rat and human liver and human endometrium and trophoblast cells. The interaction of the CBG–cortisol complex with trophoblast cell membranes causes activation of adenylate cyclase and accumulation of cAMP.

High affinity ($K_D = 6$ nM) binding of corticosterone to vole synaptic plasma membranes appears to involve one form of CBG. Specific binding to vole membranes was abolished by the saline perfusion of

brains before binding studies, and vole plasma displayed a corticosterone-binding profile similar to that of synaptic plasma membranes (see [Table 2](#)).

Signal Transduction by Membrane Glucocorticoid Receptors

Pharmacological manipulations of nongenomic glucocorticoid effects (see [Table 1](#)) have revealed some aspects of the signal transduction mechanisms by which the hormones modulate cell physiology rapidly. These signaling mechanisms are nearly as diverse as the hormone effects. Existing data indicate that glucocorticoids can initiate rapid responses via (1) modulation of intracellular Ca^{2+} , often via G-protein-mediated pathways, and (2) activation/inhibition of other signal transduction systems.

Modulation of Calcium Signaling

A large body of evidence indicates that glucocorticoids initiate rapid responses in many target cells by the modulation of intracellular calcium signaling. Cortisol inhibits N- and L-type Ca^{2+} currents in hippocampal neurons via a pertussis toxin-sensitive G-protein and protein kinase C (see [Table 1](#)). In rat brain synaptosomes, corticosterone enhances depolarization-induced Ca^{2+} influx rapidly and potentiates calmodulin-induced activation of voltage-sensitive calcium channels (see [Table 1](#)). Fish pituitary cells, rat lymphocytes, and PC12 cells respond to glucocorticoid treatment with rapid decreases in intracellular Ca^{2+} accumulation. In PC12 cells, this effect is diminished by pertussis toxin and by inhibitors of protein kinase C.

Many rapid effects of glucocorticoids are modulated by changes in extracellular calcium concentration. For example, the corticosterone-induced inhibition of vasopressin release from hypothalamic slices is potentiated in Ca^{2+} -rich medium and decreased in Ca^{2+} -depleted medium (see [Table 1](#)). The same manipulation of extracellular Ca^{2+} concentration attenuates/enhances the corticosterone-induced decrease in population spike amplitude in hippocampal neurons (see [Table 1](#)). The corticosterone-induced increase in hepatocyte glycogen phosphorylase activity is diminished in Ca^{2+} -depleted medium.

Other Signaling Pathways

A variety of other signal transduction pathways have been implicated in the mediation of rapid glucocorticoid actions. The diversity of these pathways reflects the diversity of rapid glucocorticoid actions. Roles have been proposed for rapid glucocorticoid signaling via the GABA_A receptor system, the cytoskeleton, the

cAMP and cGMP pathways, and the nitric oxide system. Certain rapid effects of glucocorticoids result from the interaction of the hormones with other membrane proteins. One such protein is the GABA_A receptor, a membrane protein complex that forms an agonist-gated chloride channel. Most studies indicate that metabolites of adrenal steroids, rather than the hormones themselves, modulate GABA_A receptor function. However, there are reports of interactions between glucocorticoids and GABA_A receptors. Glucocorticoids alter physiological responses to GABA and modulate agonist binding to the GABA_A receptor (see [Table 1](#)). Other intracellular signaling pathways have been implicated in mediating the rapid effects of glucocorticoids. In human endometrial cells, dexamethasone induces rapid actin polymerization without concomitant changes in actin synthesis, implicating the cytoskeleton as another rapid glucocorticoid effector system (see [Table 1](#)). Cortisol inhibits cAMP phosphodiesterase in bovine testis and cardiac muscle homogenates and enhances guanylate cyclase activity in various tissues, indicating other possible mechanisms of rapid glucocorticoid signaling. Inhibitors of nitric oxide synthase prevent corticosterone-induced increases in the locomotor activity of rats in a novel environment (see [Table 1](#)).

Emotion, Stress, and Memory

Emotion and Stress: Two Different Entities?

Memory for Emotionally Arousing Events

Memory after Stress

Conclusion

Glossary

<i>Acute stress</i>	Mental or bodily tension resulting from internal or external factors that tend to alter the existing equilibrium.
<i>Arousal</i>	A condition that varies in a continuum from a low point in sleep to a high point represented by intense excitement.
<i>Emotion</i>	A state of excited feeling of any kind. Basic emotions presumably are universal, are biologically based, are present from infancy, and have associated facial expressions and primitive action scripts. Basic emotions include love, joy, anger, sadness, and fear.
<i>Stress response</i>	The total set of reactions to the stressor.
<i>Stressor</i>	Any physical or psychological agent that causes the disequilibrium. Physical stressors are situations that can operate in the absence of consciousness and include disturbances of the internal environment (anoxia, hypoglycemia, etc.), external extremes (heat and cold), and physical strain (exercise or injury). Psychological stressors are situations for which there is a consciously perceived potential for harm and include stimuli that affect emotion and result in fear, anxiety, or frustration.

Emotion, Stress, and Memory

Emotionally arousing and stressful experiences are often cited as the cause of many psychological and physical problems. Many of us have experienced

emotionally arousing and stressful experiences at one point or another of our life and have noted that these experiences can have important effects on our memory. Declarative memory, which is the type of memory we refer to during the course of this article, is defined as the conscious or voluntary recollection of previously learned information. We can have forgotten an important meeting or anniversary due to work overload, or else we can have a vivid recollection of a car accident or any other emotionally arousing experience. Because of their impact on our lives, we have a tendency to pay more attention to the negative effects of stress on our memory and to forget that, under certain conditions, emotionally arousing and stressful experiences can also have a positive impact on memory function. The goal of this article is to describe the positive and negative effects of emotionally arousing and stressful experiences on memory function and to delineate the psychological and biological determinants of these effects.

Emotion and Stress: Two Different Entities?

Emotion and stress share many characteristics. A stressful experience will often cause a particular emotion (e.g., surprise, fear, or joy), and particular emotions can create stressful situations (e.g., blushing due to extreme timidity can cause a stressful situation). Moreover, an emotion possesses many of the properties of a stressor. First, it often has an identifiable source. Second, it is usually brief and leads to an intense and conscious experience of short duration. Finally, an emotion creates bodily reactions (e.g., increase in heart rate or perspiration) that are similar to those induced by a stressor, and both states act by increasing arousal. Because of these similarities between emotion and stress, most of the literature on emotion, stress, and memory intermixes the effects of emotion and those of stress on memory function. However, emotion and stress are two different entities. Although a stressful experience will almost always trigger a specific emotion, a particular emotion does not always elicit a stress reaction. As far as laboratory setting is concerned, emotion and stress differ in the way they are induced and, thus, in the way they influence memory in humans. Hence, emotions are usually induced by the presentation of emotional words, films, or pictures, whereas stress is usually induced by putting the individual in a social situation known to create a stress (e.g., public

speaking). Because of this important difference between the experimental paradigms used to measure the effects of emotion and stress on memory, different questions have been asked. The induction of emotion has been used to measure memory for emotionally arousing events, whereas the induction of stress has been used to measure the specific effects of stress on subsequent memory function.

Memory for Emotionally Arousing Events

It is well known that what we encode and remember from an event depends primarily on the attention that we devoted to this event and its components. If we do not pay attention to what we are reading right now, there is less chance that we will remember it at a later time than if we gave all our attention to a lecture. This is because the more attention given to an event, the higher the probability that this event will be elaborated (relating the information from this event to other situations and related concepts in memory) at the time of encoding. Research on memory has shown that events that are poorly elaborated (shallow processing) at the time of encoding are remembered less well than events that are deeply elaborated (deep processing) at the time of encoding.

The level of attention devoted to an event at the time of encoding will greatly depend on the emotional salience of this event. Most of us remember what we were doing and with whom we were at the time we learned about the World Trade Center attacks, but the majority of us may have difficulty remembering what we were doing and with whom we were 13 days before or after the attacks. This flashbulb phenomenon may be explained by the fact that the emotion (e.g., surprise or anger) that was triggered by the announcement of the World Trade Center attacks directed the totality of our attention to the event, leading to a deeper elaboration and, thus, to an optimization of our memory for this event.

Memory for Central versus Peripheral Details

Studies of trauma victims have reported how vividly the traumatic event is recalled in the absence of any memory for information surrounding the traumatic event. A closely analogous situation appears in the field of law enforcement and describes the weapon focus phenomenon. Witnesses to violent crimes demonstrate a weapon focus effect in which the weapon captures most of the victim's attention, resulting in a reduced ability to recall other details of the scene and to recognize the assailant at a later time. This phenomenon has been explained by Easterbrook's cue utilization theory, which suggests that emotionally

arousing events narrow subjects' attention and lead them to attend only to the center of an event and to exclude more peripheral information. In general, laboratory experiments have confirmed this hypothesis. For example, as reported by Christianson, subjects viewed a series of slides in which the emotional valence of one critical slide in the series was varied. In the neutral version, the critical slide showed a woman riding a bicycle. In the emotional version, the same woman was seen lying injured on the street near the bicycle. In both versions, a peripheral car was seen in the distant background. The results showed that the central detail information (woman and bicycle) was retained better in the emotional condition but that the peripheral information (car in background) was retained better in the neutral event. In general, the pattern of results obtained from various studies shows that the central aspects of an emotional event (those events in the scope of attention) are well retained in memory, whereas memory for peripheral details (out of the scope of attention) are poorly remembered. Recently, Cahill and collaborators pushed this analysis further and reported gender-related influences in the recall of central versus peripheral information from an emotional story. Men and women with high male-related traits on the Bem Sex-Role Inventory show better memory for central aspects of an emotional story, as opposed to peripheral details. On the other hand, women and men with high female-related traits on the Bem Sex-Role Inventory have a better memory for peripheral details of an emotional story, as opposed to central information.

Immediate versus Delayed Memory for Emotional Events

Studies have examined the relation among emotion, retention interval, and memory. What these studies have shown so far is that emotionally arousing events delay forgetting. In a highly cited 1963 study, Kleinsmith and Kaplan presented subjects with pairs of words to learn. Some of the words were neutral, whereas others had a strong emotionally negative component (e.g., rape, mutilation). The memory of the word pairs was tested 2 min or 1 week after presentation. Memory performance tested shortly after learning (i.e., short-term declarative memory) generally refers to consolidation processes occurring within the first 3 h after learning (i.e., early phase), whereas memory performance tested after an extensive delay (i.e., long-term declarative memory) generally refers to the consolidation processes taking place 3 h post-learning (i.e., late phase) and that persist for at least a day and involve gene transcription and protein

synthesis. Kleinsmith and Kaplan's study showed that at short intervals memory was poorer for emotional words, but at long intervals memory was better for emotional words. These results have been replicated many times, and the majority of studies have shown enhanced memory for emotionally arousing material, provided that memory is tested at longer retention intervals.

Possible Mechanisms Underlying the Increased Memory for Emotionally Arousing Events

Psychological as well as biological mechanisms have been suggested to explain how emotionally arousing events might enhance memory. At the psychological level, one of the most frequently cited references on the relation between emotionally arousing events and memory is the Yerkes–Dodson law. In a series of studies published in 1908, Yerkes and Dodson reported that arousal improved performance in a linear manner for easy tasks, whereas for difficult tasks they found that an inverted-U-shaped curve related better performance with medium arousal and worse performance with low or high arousal. However, many field and laboratory studies suggest that individuals retain information from high arousing events quite well, a finding that goes against the Yerkes–Dodson law predictions. Thus, Easterbrook nuanced Yerkes–Dodson arousal hypothesis, suggesting the cue utilization theory. According to this theory, increased arousal due to emotionally arousing events acts by narrowing attention to the central details of a scene, leading to better recall of central details compared to peripheral details. Based on this model, Cahill recently suggested that men's ability to better remember central emotional information was attributable to their higher use of the right amygdala when processing emotional material (the right brain hemisphere being biased for a global/holistic analysis of the information). On the other hand, women's remembering more precisely peripheral emotional information was attributable to their higher use of the left amygdala during the processing of emotional material (the left brain hemisphere being biased for local, finer analysis of the information).

Finally, Walker used the arousal hypothesis in conjunction with Hebb's concept of reverberating circuits in order to explain the retention interval effect of emotional memory. He suggested that emotional information, because it creates a high level of arousal at the time of learning, produces a more active consolidation process and leads to a stronger memory trace and better recall at longer intervals. In contrast, because it creates a high level of arousal, emotional information also acts by inhibiting recall at

shorter interval due to the fact that the process of consolidation is active (and thus inaccessible) at this time.

Contrary to psychological explanations, biological explanations of memory for emotionally arousing events have presented extensive data indicating that emotionally arousing experiences produce a retrograde enhancement of memory for that experience via a variety of hormones released during these experiences. Hence, during emotionally arousing events, there is a secretion of the peripheral catecholamines epinephrine and norepinephrine by the adrenal medulla, a secretion of central norepinephrine by the locus ceruleus and a secretion of corticosteroids by the adrenal glands. The peripheral catecholamines enhance memory by reaching the vagus nerve, nucleus of the solitary tract, and locus ceruleus. Central norepinephrine is then secreted by the locus ceruleus, activating noradrenergic neurons throughout the brain. Significantly, central norepinephrine is also triggered as soon as an emotionally arousing event occurs, independently of peripheral catecholamines. Corticosteroids, being liposoluble, enhance memory by easily crossing the blood–brain barrier and reaching the brain. Adrenergic hormones and corticosteroids may facilitate memory consolidation for emotional information through their interactions with noradrenergic and corticosteroid receptors located in the amygdala, which, in turn, modulates hippocampal activity and enhances consolidation for emotionally arousing material.

Animal and human studies have confirmed the role of these hormones in the memory-modulating effects of emotionally arousing events. Thus, in rodents postlearning stimulation of the noradrenergic system enhances (but postlearning blockade inhibits) long-term declarative memory of an inhibitory avoidance task. Likewise, posttraining injections of moderate doses of synthetic corticosteroids enhance and pretraining corticosteroid synthesis inhibition impairs long-term expression of inhibitory avoidance in animals. In humans, prelearning blockade of central β -adrenergic receptors or prelearning corticosteroid synthesis inhibition impairs long-term declarative memory for emotionally arousing material, whereas prelearning or postlearning stimulation of the noradrenergic or corticosteroid systems enhances it. Although psychological and biological explanations of the arousal hypothesis were used to explain the positive effects of emotion on memory function, research performed to this day shows that arousal is significant as an intervening variable only when the source of the arousal (in this case, the emotionally arousing event) is directly related to the information to be remembered. As we will see next, when the source

of emotion is not directly related to the information to be remembered, other psychological and biological mechanisms come into play and have a stronger impact on memory function than arousal itself.

Memory after Stress

Influences of Acute Stress on Subsequent Memory Function and Possible Psychological Effects Underlying These Influences

Remembering with great accuracy a particular emotionally arousing event is very different from performing various tasks involving memory in a day-to-day situation when we are faced with stress. We may remember with great accuracy the events in our lives surrounding the World Trade Center attacks, but we may also have forgotten the anniversary of a loved one due to work stress. Originally, the effects of a stressor on subsequent declarative memory for material unrelated to the source of stress were studied using noise as a stressor. Indeed, human beings possess a limited amount of attention that can be allocated to a particular task at any one time. Information overload is said to occur when this capacity is exceeded, that is, when there is too much information to process at the same time. When this happens, the individual may have difficulty discriminating between and attending to the relevant and irrelevant information to encode new events in memory. Studies measuring the effects of noise on memory reported that noise impairs the recall of the information encoded at the time of noise stress. This result has been interpreted as showing that noise acts by overloading the limited processing capacity of the individual, leading to impairments in processing task-relevant stimuli because of an increased distraction induced by task-irrelevant stimuli (in this case, noise). Because the individual is unable to discriminate between relevant and irrelevant information when under noise stress, memory impairment appears and is represented by a poorer recall of task-relevant stimuli.

Effects of Acute Stress on Subsequent Memory Function and Possible Physiological Mechanisms Underlying These Effects

In order to better understand the mechanisms by which stress might modulate subsequent memory processing of material unrelated to the source of the stressor, researchers aimed at defining and understanding, more specifically, memory processing, stress-related physiological activation, and the links between these two. Research over the past 40 years revealed that memory is not a unitary and passive process. In the field of cognitive psychology, the individual is viewed

as being active, constructive, and organized, not as being a passive recipient of environmental stimulation or overstimulation. Thus, the individual is seen as actively constructing a view of reality, as selectively choosing some aspects of experience for further attention, and as attempting to commit some of that information to memory. Hence, to better understand the influence of stress on subsequent memory processing of information unrelated to the stressor, it is thus necessary to determine the series of stages that make up the given act of memorization and to measure the exact effects of stress on specific components of this information processing system. Declarative memory is temporally defined in three phases; information must first be attended to (arousal and attentional processes) and encoded (short-term/working memory; phase 1) before it is consolidated (phase 2) into long-term memory and recalled (phase 3).

Physiological mechanisms have been suggested to explain the effects of stress on memory phases. The brain is the organ that gives an interpretation to a stressful experience, and it is also responsible for mounting the physiological response to the stressor. Important physiological components of the stress response include the hypothalamic-pituitary-adrenal (HPA) axis (with corticosteroids being the end product), the sympathoadrenal system, and the central noradrenergic system. The HPA axis, along with the sympathoadrenal system, governs metabolic responses to the slings and arrows of everyday life. Both these systems support a range of metabolic responses that serve to ensure the availability of sufficient energy substrates in circulation during periods when there is inevitably increased cellular activity in vital organs and an accompanying increase in the requirement for fuel. The corticosteroid system and the central noradrenergic system have been studied in relation with the memory-modulating effects of stress because these two systems, when activated, can modulate activity in noradrenergic and corticosteroid receptors in the frontal lobes, hippocampus, and amygdala, three brain structures involved in declarative memory processes.

Rodent studies have shown that when a laboratory stressor (e.g., tail shocks, water immersion, or restraint stress) is administered at various times before or after learning, as well as before recall, stress-induced elevations in corticosteroid levels modulate declarative memory according to an inverted-U-shaped function. Optimal declarative memory for material unrelated to the stressor (e.g., inhibitory avoidance protocols or spatial water-maze tasks) occur at moderate levels of stress and stress-induced increases in circulating corticosteroid levels, whereas lower (i.e., boredom or drowsiness) or higher stress

levels and stress-induced increases in circulating corticosteroid levels are less effective or may even impair declarative memory performance on these tasks.

In humans, when a laboratory stressor (e.g., a public speaking task combined with a public arithmetic task) is administered before learning or retrieval, high corticosteroid levels following stress are associated with memory impairments for material unrelated to the stressor, such as neutral words lists. Recently, studies measuring the influence of stress on memory for emotional material unrelated to the stressor reported more heterogeneous findings. Thus, when a laboratory stressor was presented before learning or retrieval of emotional and neutral information unrelated to the stressor, high corticosteroid levels following stress were associated with memory impairments for emotional information (whether positive or negative), whereas they had no influence on memory for neutral material. However, two other studies showed that stress administered before or after learning enhanced memory for emotional material, whereas it had no impact or impaired subsequent memory for neutral information.

Altogether, these results show that stress-related elevations in corticosteroids can have different effects on subsequent memory for material unrelated to the stressor. The effects of emotionally arousing and/or stressful events on declarative memory vary according to the nature of the material to be remembered, with elevated levels of corticosteroids enhancing memory for the emotionally arousing event itself but leading, more often than not, to memory impairments for material unrelated to the source of the stressor.

The time of day (morning vs. afternoon) and levels of circulating corticosteroids at the time of testing could also be important factors influencing the effects of stress-related elevations in corticosteroids on subsequent memory for material unrelated to the stressor. Corticosteroid receptors differ in terms of their affinity for circulating levels of corticosteroids. Mineralocorticoid receptors (MRs) have a 6- to 10-time higher affinity for corticosteroids than glucocorticoid receptors (GRs). A wealth of evidence now demonstrates that the activation of MRs is mandatory for the successful acquisition of environmental cues necessary to encode information, whereas the activation of GRs is necessary for the long-term memory consolidation of this information.

Endogenous levels of corticosteroids and, thus, the activation of the MRs and GRs, significantly vary during the day, with higher endogenous levels of corticosteroids in the morning (AM) phase than in the evening (PM) phase. Consequently, the addition of a stressful and emotionally arousing event, which

by itself will trigger a significant increase in the endogenous levels of corticosteroids, should have a differential impact on the activation of MRs and GRs as a function of time of day. In the AM phase, most of the MRs and approximately half of the GRs are activated, whereas, in the PM phase, most of the MRs and about one-tenth of the GRs are activated. If we apply a stressor in the AM phase, the endogenous increase in corticosteroid levels will act by saturating GRs, but the same stressor applied in the PM phase will act by activating approximately half of the GRs. Because stress-induced elevations in corticosteroid levels have been shown to modulate declarative memory for material unrelated to the stressor according to an inverted-U-shaped function, the differential activation of MRs and GRs at different times of the day imply that a stressor applied in the morning should impair memory function (right-hand-side of the inverted U-shaped curve), whereas the same stressor applied in the PM phase should increase or have no impact on memory (left-hand-side or top of the inverted-U-shaped curve). Moreover, given that stress has differential effects as a function of the emotional valence of the material to be learned, it can be suggested that the application of a stressor in the AM versus PM phase should have a different effect on memory for emotionally arousing or neutral information unrelated to the source of the stressor.

Individual differences could also be an important factor explaining the discrepancy in the effects of stress-related elevations in corticosteroids on subsequent memory for material unrelated to the stressor. Indeed, high and low corticosteroid responders can show different memory performance following stress. Individual differences could be attributable to genetic factors, corticosteroid sensitivity differences and lifespan cortisol exposure differences, gender, or personality.

Finally, very few studies measured the influence of the central noradrenergic system, activated following stress, on subsequent memory for material unrelated to the stressor. Animal studies reported that stress-induced elevations in norepinephrine levels (following foot shocks) modulate declarative memory according to an inverted-U-shaped function, with optimal levels enhancing (and lower or higher levels of norepinephrine impairing) memory for information unrelated to the source of stress (e.g., passive aversive conditioning). In humans, one recent study showed that the blockade of peripheral and central noradrenergic β receptors before the administration of a stressor did not impair memory for material unrelated to the source of stress. These results suggest that the β -adrenergic system is not implicated in the effects of stress on subsequent declarative memory

function, contrasting with the well-established role of this system during the memorization of events that are emotionally arousing in nature. Further studies in humans are needed to determine the exact role played by the central noradrenergic system in the effects of stress on subsequent memory for information unrelated to the stressor.

Conclusion

In sum, important differences in mnemonic performance exist between memory for emotionally arousing events and memory for material unrelated to a stressor that is processed after stress. Interestingly, whether the subject is memorizing the emotionally arousing event itself or material unrelated to the stressor, both the central noradrenergic system and the corticosteroid system are at play, although they seem to act differently in the recall of neutral and emotional information. Experimental factors (e.g., nature of material to remember and time of day) and individual differences (e.g., personality and genetics) are also important components to consider because they can all influence the direction of the effects of emotion and stress on memory. Future studies considering and controlling for these factors and measuring the interactive and/or differential effects of the noradrenergic and corticosteroid systems should prove highly valuable to our understanding of the effects of emotionally arousing and stressful experiences on human declarative memory processes.

Memory in Posttraumatic Stress Disorder
Other Stress-Related Memory Disorders
Neurophysiological and Neuroanatomical Aspects of the
Effect of Stress on Memory
Summary

Glossary

Declarative memory Any memory task that requires a subject to retrieve a specific past event; used interchangeably with explicit memory and episodic memory.

Episodic memory Any memory task that requires a subject to retrieve a specific past event; used interchangeably with explicit memory and declarative memory.

Explicit memory Any memory task that requires a person to retrieve a specific past event; used

Flashback

interchangeably with declarative memory and episodic memory.

Sudden reemergence of a traumatic memory that has previously been inaccessible; characteristic of posttraumatic stress disorder (PTSD).

Fugue

Stress-induced loss of memory in which the person loses personal identity and may even assume a new one.

Hippocampal formation

Name given to the hippocampus proper plus associated structures, including the dentate gyrus and entorhinal cortex.

Hippocampus

Region of the medial temporal lobes involved critically in the formation of new memories. Particularly vulnerable to the effects of cortisol but also to other neuromodulators that increase with the onset of stress.

Hysterical amnesia

Loss of memory for a specific period associated with trauma. Difficult to distinguish from PTSD.

Implicit memory

Any memory task that tests a person's memory for an event without direct reference to that event; used interchangeably with nondeclarative memory and sometimes with procedural memory.

Multiple personality

Memory disorder associated with history of abuse. If genuine, it is thought to be linked to stress, but many believe it has a strong iatrogenic component.

[†]Deceased.

<i>Nondeclarative memory</i>	Any memory task that tests a person's memory for an event without direct reference to that event; used interchangeably with implicit memory and sometimes with procedural memory.
<i>Priming</i>	A widely used measure of nondeclarative memory in which prior exposure of a stimulus can facilitate subsequent processing of that stimulus without the subject's awareness.
<i>Procedural memory</i>	Strictly speaking, this defines any form of memory that is not subject to conscious access but is sometimes used interchangeably with implicit memory and nondeclarative memory.
<i>Trier social stress test</i>	A widely used experimental manipulation for increasing stress in which subjects undertake a public-speaking exercise.
<i>Wechsler memory scale revised</i>	The most widely used instrument for assessing deficits in declarative memory. It tests both verbal and nonverbal memory.

Memory in Posttraumatic Stress Disorder

Posttraumatic stress disorder (PTSD) is now a recognized condition that presents in an individual following a traumatic event. It is observed most commonly in combat veterans but can also be found in people who have been involved in accidents, been the victim or witness of a violent event, or been subjected to sexual abuse as a child. The effects of PTSD on memory are somewhat complex. Typically the sufferer is amnesic for the traumatic experiences, but, from time to time, flashbacks occur in which the traumatic experience is recreated vividly in the individual's mind. It is not clear what determines the occurrence of a flashback, but one determining factor appears to be mood. Memory is known to be sensitive to state dependency in that a memory is more likely to be retrieved if the individual's mood state matches that experienced at the time of the traumatic experience. There is also some suggestion that the recall of traumatic memories has a dissociative quality in that the person attributes the traumatic recall to an aspect of their self that is in some way detached from their normal ongoing self.

There is now abundant evidence that PTSD victims also have an impaired ability to remember new information. For example, Vietnam veterans with PTSD performed more poorly than controls on components of the Wechsler Memory Scale, and this type of effect has been shown on a variety of other tests of memory. Adolescent victims of violence in Beirut with PTSD

have been shown to achieve lower academic performance than their counterparts without PTSD. Victims of PTSD also exhibit memory gaps ranging from minutes to hours. Examples include one person who remembered nothing between walking down a street in Boston and waking up in Texas and another who disappeared from a psychiatric unit and then awoke to find himself in battle dress in the woods. Also, consistent with the state dependency view of PTSD, victims of PTSD show a greater recall of trauma-related words but a poorer recall of neutral and positive affect words.

Other Stress-Related Memory Disorders

While PTSD is the most prominent psychiatric disorder of memory linked to stress, there are other conditions that have rather different qualities. The first of these is what has been termed hysterical amnesia. There are great similarities here with PTSD in that the patient has a temporary loss of memories for a particular adverse event. The only difference is that the disorder appears associated with less overall psychiatric morbidity than PTSD.

Far less common, although a great favorite with fiction writers, is the fugue state. In this dissociative disorder the patient loses his or her identity and, in many cases, assumes a new one. There are very few detailed studies of fugue because the condition can ameliorate quite quickly and a number of cases turn out to be malingering. However, in a well-documented case, a young man was deeply disturbed by the death of his grandfather and remained in a fugue state for some time, exhibiting only fragments of memory about his own past. However, while watching the funeral scene in the film *Shogun*, his memory of himself came back, again stressing the importance that state dependency may play in the mediation of stress-related memory dysfunction.

Stress can also be implicated in perhaps the strangest of memory disorders – multiple personality disorder (MPD). Here the person assumes a number of different personalities that have differing relationships with one another. Thus, personality A may know about personality B but not vice versa, and so on. There is massive controversy about MPD, and many clinicians believe that the condition is essentially iatrogenic – generated by clinicians in suggestible clients and also faked by knowledgeable individuals, a good example being the famous case of the hillside strangler. Taking a more moderate view, it is possible to argue that in genuine cases of MPD, various personalities absorb different aspects of a stressful past. In one case, for example, a young woman had a

history of sexual abuse and drug taking. Discussion of these different aspects of her past was only possible via different personalities that she presented.

Neurophysiological and Neuroanatomical Aspects of the Effect of Stress on Memory

There is now a great deal of knowledge about why stress can cause a loss of memory function. Stress is known to increase the levels of glucocorticoids, which in turn has adverse effects on memory. There is a disorder known as the Morbus-Cushing syndrome that results in abnormally high levels of cortisol production; patients with this disorder exhibit memory dysfunction as one of their primary symptoms. Cortisol is widely held to exert its adverse effects on a brain region known as the hippocampus. This structure, located bilaterally in the medial temporal lobes, is critically involved in the initial consolidation of memory and is also thought to mediate the storage of memories for some time after their initial registration. Animal studies have shown that increased cortisol levels result in a loss of hippocampal neurons and in a decrease in dendritic branching. This loss is thought to be attributable to an increased vulnerability of the hippocampus to endogenously generated amino acids. Further evidence for the effects of cortisol on the hippocampus comes from studies showing that a major physiological index of hippocampal function, long-term potentiation, is affected by the administration of cortisol.

Further evidence for cortisol involvement in stress-related memory dysfunction comes from work involving the endogenous indole isatin, which exists in particularly high levels in the hippocampus and cerebellum. At relatively low levels it has an anxiogenic effect and results in an increase in circulating levels of cortisol. It also negates the anxiolytic effects of atrial natriuretic peptide and its associated memory enhancement effects.

Other research also points toward a critical relationship between stress and hippocampal function. Monkeys exposed to stress as a result of overcrowding were found to have hippocampal damage, and there is similar evidence in humans. One study used magnetic resonance imaging to compare hippocampal volume in Vietnam veterans with PTSD and healthy subjects. The PTSD veterans were found to have an 8% reduction in the volume of the right hippocampus, with no changes in adjacent brain structures. Similarly, with positron emission tomography, Vietnam veterans with PTSD were found to have a reduced blood flow in the hippocampus, again indicating a degree of malfunction. The same research

group has found a selective 17% reduction in the left hippocampus of adult survivors of sexual abuse.

The just-mentioned studies point to permanent changes in brain structure caused by stress and are presumably mediated, at least in part, by prolonged exposure to elevated cortisol levels. However, there is also evidence that increased cortisol levels can also cause temporary memory impairment. In one study, human volunteers were administered the synthetic steroid dexamethasone. The volunteers were then given two types of memory test involving either declarative memory or nondeclarative memory. Declarative memory is what we typically think of as memory – the ability to remember lists of words, recognize faces, and so on. The effect of dexamethasone was to reduce the performance on this type of memory dramatically. Unlike declarative memory, where the individual has to reflect directly on a previous event, nondeclarative memory tests an individual's retention indirectly. A favorite method is known as priming. Here a subject is exposed to a list of words and is asked, for example, to rate each word for pleasantness. No mention is made of having to remember any of the words. Subsequently, the subject is given a test, such as "Tell me the first word that comes to mind beginning with the letters PL." If the word placid was in the previous word list, there is a strong probability that this word will be generated in preference to other possibilities. This indicates that the subject has retained information about the word list. Interestingly, these effects appear independent of subjects' declarative memory and are shown reliably by people who have a dense amnesia for declarative information. The administration of dexamethasone did not affect nondeclarative memory. This type of effect has been reported in other studies and indicates that the effects of glucocorticoids are limited to declarative memory and, by implication, that the hippocampus, with its vulnerability to enhanced cortisol levels, is not involved in nondeclarative memory performance.

Aging has been associated with an increased vulnerability to stress, which has led to the possibility that the effects of age on memory may, in part, be mediated by cortisol levels. One study employed the Trier social stress test. Essentially, this test involves subjects being asked to speak in public as a means of inducing variable amounts of stress depending on the individual. Fear of public speaking was found to enhance cortisol levels in varying degrees, which in turn predicted recall performance, with higher cortisol levels predicting poorer recall. A comparable non-stressful task had no effect on performance. Interestingly, the best predictor of the relation between cortisol levels and memory performance was a

measure obtained 60 min before the stressful event, thus indicating that the anticipation of stress is a crucial factor in determining memory performance.

While this account has emphasized the role of stress on memory via changes in cortisol levels, a variety of other neurotransmitters and neuropeptides are released during stress. These include adrenocorticotrophic hormone (ACTH), dopamine, acetylcholine, endogenous opiates, vasopressin, oxytocin, and γ -aminobutyric acid. Of these, vasopressin and oxytocin are of particular interest in relation to the occurrence of flashbacks in PTSD. One study used a structured imagery technique designed to solicit the retrieval of traumatic memories in Vietnam veterans. The administration of vasopressin enhanced the recall of trauma, whereas oxytocin inhibited trauma recall, relative to the placebo.

A final issue is whether the available research on stress and memory has any bearing on the false memory debate. This debate has caused enormous controversy – the central point being whether memories of abuse could remain buried for years and then suddenly reemerge. Available evidence certainly makes an *a priori* case that the stress caused by continual abuse would be expected, via the mediation of cortisol, to have a deleterious effect on an individual's recall for the period of abuse. What is less clear is whether the mechanism used to account for flashbacks in PTSD could be adapted to explain recovered memory. It is a very problematic issue, not in the least because there is abundant evidence that so much recovered memory is generated by inappropriate hypnosis-based memory work induced by very biased therapists.

Summary

Stress has a range of effects on memory, ranging from minor lapses of memory in normal individuals to the sometimes devastating effects of PTSD. The major change in brain anatomy associated with prolonged exposure to stress is shrinkage of the hippocampus.

This is widely attributed to increased cortisol levels experienced during stressful periods.

PTSD, the most notable stress-related memory disorder, is characterized by impaired declarative memory and normal nondeclarative memory. Other stress-related memory disorders are hysterical amnesia, fugue, and multiple personality disorder. Transient increases in cortisol levels induced either synthetically or via stress induction procedures result in impaired declarative memory but normal nondeclarative memory. The sudden and vivid availability of traumatic memories in PTSD may be due to the special influence of vasopressin, which is also released during periods of stress.

Menopause as a Stressful Life Event

Impact of Stress on Menopause Symptomatology

Stress and Ovarian Function

Conclusions

Glossary

<i>Menopause</i>	The permanent cessation of menses. The standard epidemiological definition of natural menopause is 12 consecutive months of amenorrhea, in the absence of surgery or other pathological or physiological cause (e.g., pregnancy, lactation, excessive exercise).
<i>Perimenopause</i>	That period of time immediately prior to menopause when the endocrinological, biological, and clinical features of approaching menopause begin through the first year after the final menstrual period. It is characterized by increased variability in menstrual cycles, skipped menstrual cycles, and hormonal changes. Early perimenopause is defined as menses in the previous 3 months, but changes in regularity. Late perimenopause is defined as no menses in the previous 3 months, but menses in the preceding 11 months.
<i>Premenstrual syndrome (PMS)</i>	A disorder characterized by a set of hormonal changes that trigger disruptive physical and emotional symptoms in a significant number of women for up to 2 weeks prior to menstruation.
<i>Surgical menopause</i>	Menopause induced by a surgical procedure that stops menstruation. Women who have both ovaries or the uterus with or without removal of the ovaries are generally included in this category.

Menopause as a Stressful Life Event

Whether or not menopause is viewed as a stressful life event can be looked at in two ways: (1) women's attitudes toward menopause, and (2) women's affective responses to menopause.

Attitudes toward Menopause

Cross-cultural and anthropological studies provide evidence that the meaning of menopause varies greatly across cultures. How a society views menopause is influenced by how it views aging and women in general. Menopause is often viewed as a positive event in women's lives in non-Western cultures, where menopause removes constraints and prohibitions imposed upon menstruating women. In countries where women have low status or are not allowed to show sexuality (such as in India), menopause is seen positively, as it provides freedom to go out in public and do things usually forbidden to women. Among South Asian women, the end of childbearing and the menstrual cycle is welcomed. While social status is tied to motherhood, it is motherhood that is valued and not biological fertility itself.

Among both Mayan and Greek women, menopause is seen as a positive event, although for different reasons. Mayan women marry young, do not practice birth control, and spend most of their reproductive years either pregnant or lactating. Pregnancy is viewed as dangerous and stressful, and menopause frees women from restrictions and pregnancy. While Greek women attempt to curtail family size and often use abortion as a means of birth control, menopause also frees Greek women from taboos and restrictions. A postmenopausal Greek woman is allowed to participate fully in church activities, as she is no longer viewed as a sexual threat to the community. Both Mayan and Greek women report better sexual relationships with their husbands following menopause, as the fear of pregnancy is eliminated. In other cultures, women give menopause little thought. In Papago culture, menopause may be completely ignored, to the extent that the language contains no word for menopause. In Japan there is no word to describe hot flashes. As Lock points out, the lack of a Japanese word to describe hot flashes is remarkable in a language that is infinitely more sensitive than English in its ability to describe bodily states (e.g., there are more than 20 words to describe the state of the stomach).

In Western societies, women are valued for sexual attractiveness and do not face restrictions found in other cultures. Aging, especially among women, is not revered, but rather is viewed quite negatively. In these societies menopause takes on a very different meaning. Despite these negative societal views, women themselves do not hold such negative attitudes.

A review of research on women's attitudes toward menopause conducted across a wide range

of populations and cultures shows that women consistently feel relief about the cessation of menses and do not agree that they become less sexually attractive following menopause. Women consistently report that they are glad to no longer deal with menstruation, accompanying PMS or menstrual cramps, fear of pregnancy, and purchase of feminine products. Thus, the end of menstruation, rather than bringing on a sense of psychological loss, is often met with relief. While women may feel a decrease in sexual desire or frequency, which they attribute to aging as much as to menopause, women overwhelmingly disagree with the statement that postmenopausal women are less feminine or attractive. Studies consistently show that postmenopausal women generally have a more positive view of menopause than premenopausal women. Thus, women's own attitudes toward menopause are not as negative as those of the medical profession or Western societies as a whole.

Women's Response to Menopause

Another way to examine whether menopause can be viewed as a stressful life event is to look at the impact of menopause on mental health. Earlier reports based on patient or clinic populations often perpetuated the perception that women become depressed and irritable and suffer a host of other symptoms during menopause. These studies, however, suffered from numerous methodological problems. First, such patient-based samples are highly biased. Fewer than half of menopausal women seek treatment, and those who do tend to report more stress in general and suffer more from clinical depression, anxiety, and psychological symptoms than nonpatient samples. Second, these studies often did not differentiate between women who experienced surgical and those who experienced natural menopause. Women who undergo surgical menopause have a very different experience of menopause, in that they experience more sudden hormonal changes, as well as a surgical procedure. A number of studies have found that women who have had a surgical menopause report more distress than women who experience a natural menopause. Finally, these studies often used menopausal checklists that asked women to check off symptoms that they experienced due to menopause. When asked in this way, women will check off any symptom they have that fits their beliefs about what women experience during menopause. This method thus perpetuates existing stereotypes of the menopause experience.

Cross-sectional epidemiological studies of community-based samples of women do not show consistent evidence of a relation between menopause and depression or other negative moods in the general

population. More recently, several longitudinal studies have shown an increased risk of depressive symptoms during perimenopause. However, it is important to note that only a minority of women appear to experience an increase in negative mood or depression during perimenopause, and other factors, such as stress and socioeconomic factors, are more related to depressed mood than hormones or menopausal status. Longitudinal data suggest that prior depression is the primary factor related to depression during menopause. Studies have also found that women who report greater mood disturbances at menopause also report menstrual cycle or reproductive-related problems. These include previous or current premenstrual symptoms or complaints, dysmenorrhea, and postpartum depression. Researchers have also found that social circumstances and stress account for much of the mood effects during the menopause transition. Studies that have included measures of stress or life changes have typically found that social factors are highly related to mood, and often more so than menopause status.

Thus, for the majority of women, menopause does not appear to be a stressful life event. However, like other life events or changes, this does not mean that menopause is not stressful for some women. It has been hypothesized that women who find menopause stressful are those who see it as the end of reproduction or a sign of old age. Women with less education or knowledge about menopause generally have more negative attitudes, as do women who have more symptoms in general or worse mental health.

Impact of Stress on Menopause Symptomatology

Vasomotor symptoms (hot flashes/flushes and night sweats) are the primary symptoms associated with menopause. Estimates of the incidence of hot flashes from population studies in the United States and worldwide have ranged from 24 to 93%. Studies of menopause in different cultures reveal wide cultural variation in symptom reporting. For example, hot flashes are uncommon in Mayan women, and Japanese and Indonesian women report far fewer hot flashes than women in Western societies. Because women across cultures differ in terms of their diet, physical activity, number of pregnancies, use of contraception, as well as attitudes toward menopause, it has been difficult to assess the reason(s) for this variation. However, even within a culture, a high degree of variability of symptom reporting is found among women, suggesting considerable individual variation in symptom experience. What differentiates symptomatic from asymptomatic women is not well understood.

Women experiencing other sorts of stress are likely to notice or amplify menopausal symptoms, as they would any symptom. Epidemiological studies have shown greater vasomotor symptoms associated with less education, interpersonal stress, more general symptom reporting, and negative attitudes toward menopause. A relationship between stress and hot flashes has been shown in several correlational and treatment studies. One study has shown that laboratory-induced stressors correlate with women's objectively measured hot flashes. However, hot flashes did not concentrate around the actual stressor, suggesting that stress may potentiate (rather than cause) hot flashes by decreasing the threshold for the triggering of hot flashes at the hypothalamic level. Findings that women who report more symptoms premenopause also report more menopausal symptoms are consistent with the notion that some people have greater sensitivity to symptoms.

Thus, consistent with other research on stress and symptoms, there is some evidence that women experiencing stress for other reasons may have a tendency to notice or report greater menopausal symptoms. However, stress is only one of many factors that appear to impact menopausal symptoms.

Stress and Ovarian Function

Impact of Stress on Ovarian Function

Appropriate secretion of hypothalamic gonadotropin-releasing hormone (GnRH) is necessary for ovarian cyclicity. Decreased GnRH is a common cause of anovulation. Research in both humans and monkeys suggests that stress desynchronizes the GnRH neuronal network. High levels of stress have been shown to lead to altered menstrual function in premenopausal women. The impact of stress on perimenopausal women has not been well studied, but there is some evidence that marked increases in stress may alter menstrual cycles in the short term. It has also been hypothesized that high levels of stress may accelerate menopause. Recent research, however, has shown conflicting findings, with one study finding some evidence that stress accelerated menopausal age among women who were already experiencing irregular cycles or who were African-American, and another study finding that women who reported more psychological symptoms had a longer perimenopause.

Ovarian Function and Stress Responsivity

It has also been hypothesized that reproductive hormones influence the response to stress. Several researchers have examined the impact of ovarian

function on reactivity to stress. These studies have largely examined cardiovascular reactivity in response to laboratory stresses among women in differing stages of ovarian functioning. While studies have shown greater responses among postmenopausal or surgically menopausal women as compared to premenopausal women, more recent research among women with experimentally suppressed ovarian function has not shown greater responses to stress. This remains an area of investigation.

Conclusions

Although menopause itself is a physiological event, a woman's response to menopause depends on cultural, behavioral, psychosocial, as well as physiological factors. How an individual woman responds to menopause is a complex interaction of physiology, her current life circumstances, attitudes/concerns about fertility, the culture in which she lives, and her history of responding to physiological changes/symptoms. On the whole, menopause is not a stressful event for most women. Concurrent stresses from other sources, however, may exacerbate a woman's response to menopausal symptoms.

Biological Effects of Stress on Menstruation

Anorexia Nervosa and Amenorrhea

Exercise, Stress, and the Menstrual Cycle

Effects of Menstrual Cycle on Stress, Mood, and Psychiatric Symptoms

Consequences of Amenorrhea

Treatment Issues

Glossary

<i>Amenorrhea</i>	The absence of menses for 3 months or longer.
<i>Anorexia nervosa</i>	An eating disorder characterized by the refusal to maintain a minimally normal body weight; symptoms also include the absence of at least three consecutive menstrual cycles.
<i>Corticotropin releasing hormone (CRH)</i>	A 41-amino-acid peptide secreted by the paraventricular nucleus of the hypothalamus, which stimulates pituitary secretion of adrenocorticotrophic hormone and, consequently, cortisol secretion by the adrenal cortex.
<i>Functional hypothalamic amenorrhea</i>	Amenorrhea associated with factors such as psychogenic stressors, excessive exercise, or weight loss.
<i>Gonadotropin-releasing hormone (GnRH)</i>	A decapeptide hormone that plays a significant role in reproductive physiology through stimulation of follicular stimulating hormone and luteinizing hormone by the pituitary. GnRH is secreted by neurons of the preoptic and arcuate

nuclei of the hypothalamus in a pulsatile manner, with the amplitude and frequency of its secretions under the regulation of estrogen, progesterone, catecholamines, and neuropeptides.

Secondary amenorrhea

Amenorrhea that occurs when the patient has menstruated in the past but has stopped for at least 3–6 months. Causes can include pregnancy, lesions of the hypothalamus or pituitary (from surgery, infection, irradiation, chemotherapy, infarction, or tumor), emotional stress, endocrine disease (e.g., thyroid, adrenal, or diabetes), or medications.

Stress can be conceptualized as a state of disharmony or threatened homeostasis, with the patient's adaptive response being specific to the stressor or being more generalized. Although the demands and complexity of society continue to increase, the physiological mechanisms for coping with adversity have not changed appreciably over the past thousands of years, and the physiological responses to social pressures, rapid changes, and increased information are often similar to responses to physical danger and threats to survival. The effects of stress can be profound, resulting in the mobilization of adaptive behaviors and peripheral functions and the inhibition of biologically costly behaviors such as reproduction. For many animals, environmental stress, or conditions of high population density, are associated with chronic anovulation and infertility. During unfavorable circumstances, the lack of reproduction allows females to focus scarce resources on survival, improvement in overall condition, and investment in existing offspring. Although animal studies have provided information on the hormonal pathways through which stressors impact reproductive function, these mechanisms are poorly understood in humans. Nevertheless, for women, psychosocial stressors such as bereavement or separation from family, in the absence of a psychiatric diagnosis, have been linked to abnormalities of the menstrual cycle. Rates of menstrual irregularities increase in proportion to chronic stress, which, if severe enough, can completely inhibit the female reproductive system. Although the nature of the actual stressor can be significant, the response of the individual to the stressor, as well as certain cognitive, behavioral, or personality traits, may cause some women to be more vulnerable to the stress of daily living than other women and may play a more significant role in affecting menstruation than the actual stressor itself. The impact of stress can range from a lack of menstrual cycles to persisting cycles of marginal quality.

The Menstrual Cycle

The menstrual cycle is defined by the regular, repetitive monthly occurrence of ovulation throughout a woman's reproductive life. Menarche, defined as the onset of the first menses, occurs in the United States between the ages of 9 and 12, with a mean of 12.6 years. The mean duration of the cycle is 28 days, and the cycle is divided into two functional phases: the follicular (or proliferative) phase and the luteal (or secretory) phase. Polymenorrhea refers to menstrual cycles that occur at intervals of less than 21 days, whereas oligomenorrhea describes menstrual cycles occurring at intervals greater than 35 days. Menstrual cycles tend to be most irregular in the first 2 years after menarche and in the 3–5 years before menopause (perimenopause).

The follicular phase of the menstrual cycles starts at the first day of menses, continues until ovulation, and is characterized by a variable length, low basal body temperature, development of ovarian follicles, vascular growth of the endometrium, and the secretion of estrogen from the ovary. The luteal phase begins with ovulation, continues until the beginning of menses, and is characterized by a relatively constant duration of 12–16 days, an elevated basal body temperature, the formation of the corpus luteum in the ovary with the secretion of progesterone and estrogen, and preparation of the endometrium for implantation of an embryo.

Regular menstrual cycles occur as a result of complex, coordinated interactions among the central nervous system, the hypothalamus, the pituitary, and the ovary. Specifically, menstrual cyclicity occurs as a result of the pulsatile secretion of gonadotropin-releasing hormone (GnRH) by neurons in the preoptic and arcuate nuclei of the hypothalamus. GnRH then acts on the pituitary to stimulate release of the gonadotropins luteinizing hormone (LH) and follicular stimulating hormone (FSH), which influence the selection and maturation of the follicle for ovulation as well as secretion of ovarian steroid hormones that act on the genital tract. GnRH is secreted in a pulsatile manner at approximately 1 pulse per h in the follicular phase and 1 pulse per 2–3 h in the luteal phase, and the amplitude and frequency of secretions are influenced by feedback from estrogen and progesterone as well as catecholamines, dopamine, and norepinephrine within the brain. Estrogen levels rise in the follicular phase, reaching a peak approximately 24–36 h before ovulation. LH increases steadily until the midcycle when there is a surge, and ovulation occurs approximately 10–12 h after the LH peak. In the absence of pregnancy, decreasing steroid levels result in the constriction of the arteries

supplying the upper two-thirds of the endometrium, with subsequent shedding of the degraded endometrial tissue.

Biological Effects of Stress on Menstruation

Amenorrhea is defined by the absence of menses for 3 or more months. The failure of menarche to occur is referred to as primary amenorrhea; secondary amenorrhea refers to the discontinuation of menses after the onset of menarche. Prevalence rates for secondary amenorrhea range from 8.5% among women ages 13–18 years, 7.6% among women ages 15–24 years, and 3% among women ages 25–34 years.

Identifiable or organic causes of secondary amenorrhea and anovulation include a pituitary adenoma or hypothalamic tumor; however, the most common cause of amenorrhea is not the result of an identifiable organic source but is, rather, associated with psychological and lifestyle variables, including excessive exercise, low weight, affective and eating disorders, substance use, and stress. This condition is known as functional hypothalamic amenorrhea (FHA). The function of the hypothalamus is to maintain homeostasis and promote adaptation by regulating the neuroendocrine axis. It receives afferent neural information from other brain areas, as well as signals from the periphery that cross the blood-brain barrier, and then releases hormones that influence the synthesis and release of specific pituitary hormones in an integrated fashion, coordinating endocrine responses with internal and external demands. Changes in activity at one hypothalamic area can result in profound changes in the function of other areas. Psychophysiological factors, for instance, affect central neuroregulatory networks that subsequently disrupt the GnRH pulse generator and impact reproductivity. Specifically, stress can result in a decrease in GnRH drive, with the frequency and amplitude of the pulsatile release of GnRH falling out of the normal range. In general, catecholamines, epinephrine, and norepinephrine increase GnRH release, whereas β -endorphins decrease GnRH release. Although plasma concentrations of GnRH are too low to measure, LH levels correlate well with those of GnRH, and its secretory patterns can be used for information on hypothalamic-pituitary-gonadal (HPG) activity. LH pulses normally have a constant amplitude with a frequency of 2–6 h in the follicular phase and a more variable amplitude with a frequency of 2–6 h in the luteal phase. Studies have shown that, in women with the presence of both a stressful life event and a psychiatric diagnosis, spontaneous LH pulse

frequency is inhibited. A study of 67 patients with hypothalamic secondary amenorrhea found that the onset of the menstrual disorder was correlated with a psychosocial stressor in close to half of the patients. When both a psychiatric diagnosis and a stressful life event are present, LH pulse frequency can be reduced by as much as 50% of that for normally menstruating women. Studies have also demonstrated that the presence of an anxiety or depressive disorder reduces pulse amplitude significantly. However, for women with amenorrhea without a psychiatric disorder or a stressful life event, the pulsatile release of LH is similar to that in normally menstruating women in the follicular phase. Thus psychogenic factors appear to influence LH release, reflecting effects on HPG activity and GnRH secretion. With significant declines in pulsatile GnRH secretion, the pituitary secretion of LH and FSH is reduced, compromising folliculogenesis and ovulation.

A possible mechanism that may link the GnRH pulse generator and stress involves the hypothalamic-pituitary-adrenal (HPA) axis, which is activated by stress. Women with secondary amenorrhea often display hypercortisolism, and in monkeys and rats, the administration of corticotropin releasing hormone (CRH) results in an acute decrease in pulsatile GnRH and gonadotropin release. CRH also inhibits LH by central effects, partially mediated by central endogenous opiates. Stress stimulates the expression of CRH and vasopressin. In monkeys, vasopressin has been shown to decrease LH secretion acutely when administered intracerebroventricularly.

Further evidence suggesting involvement of the HPA axis has been provided by Berga, who demonstrated that cortisol concentrations, which reflect HPA activity, are elevated in women with FHA. In women with other causes of anovulation, cortisol concentrations were found to be comparable to those observed in women who were eumenorrheic with biochemical evidence of ovulation. Women with FHA who resumed ovulation had cortisol concentrations similar to eumenorrheic women and lower than women with persistent FHA.

Anorexia Nervosa and Amenorrhea

Much of the literature on stress and menstruation focuses on women with anorexia nervosa. Anorexia nervosa is characterized by a refusal to maintain body weight at or above the minimally normal weight for age and height, an intense fear of gaining weight even though underweight, disturbance in the way in which one's body weight or shape is experienced, and the absence of at least three consecutive menstrual cycles.

The disorder has a prevalence rate of 0.5–1.0% among females of late adolescence and early adulthood, although individuals with eating disorders that do not meet the full criteria for anorexia are more common. Anorexia accounts for 15–34.5% of patients with amenorrhea.

Clinical traits of anorexia often include an obsessive preoccupation with dieting, a desire to regress to prepubertal body habits to disguise femininity, and intense, obsessive-compulsive personality traits that result in hyperachievement. Mean age of onset for the disorder is 17 years, with possible bimodal peaks at ages 14 and 18. The onset of illness is often associated with a stressful life event, such as leaving home for college or the breakup of a relationship. The onset of dieting may be related to the stressor or may begin more insidiously, and amenorrhea can precede or be associated with weight loss. Unless the psychological stress is also addressed, menstrual cycles can remain abnormal, despite adequate weight gain. Follow-up studies at 2 years have found that psychological impairment persists in one-third to one-half of patients, with one-third of patients experiencing recurrent affective disorders and one-fourth of patients not regaining menses or attaining 75% of ideal body weight.

Females with anorexia nervosa demonstrate a pattern of 24-h gonadotropin secretion that is similar to prepubertal girls, with reversion to adult patterns following adequate weight gain and a change in behavior. Compared with normally menstruating women, the LH response to GnRH is diminished in the follicular phase. For women with secondary amenorrhea or infertility and weight loss, but without anorexia, similar but less severe changes in LH are seen.

Exercise, Stress, and the Menstrual Cycle

Strenuous, regular physical activity has also been associated with menstrual irregularities, oligomenorrhea, amenorrhea, or delayed menarche. Up to 50% of competitive runners, 25% of recreational runners, and 12% of cyclists and swimmers demonstrate amenorrhea. Both weight loss and stress have been implicated in the cause of exercise-associated amenorrhea through the disruption of GnRH secretion. Stress can be metabolic, psychological, or a combination of both, and its effects may be partly mediated by the increased β -endorphin levels that impact the amplitude and frequency of LH pulses. In addition, the release of CRH in endurance exercise can inhibit gonadotropin secretion and activate the release of corticosteroids and androgenic steroids.

Although psychological stress may result in erratic menstrual cycles, its role in exercise-related amenorrhea appears to involve initiation more than continuation.

Effects of Menstrual Cycle on Stress, Mood, and Psychiatric Symptoms

In addition to the influence of stress on the menstrual cycle, monthly fluctuations of reproductive hormones can impact a woman's vulnerability to the experience of stress. Some studies, for example, reported a four-fold increase in the prevalence of suicide attempts and allergic bronchial asthma attacks in the late luteal phase of the menstrual cycle.

The levels of estrogen, progesterone, and their metabolites fall during the late luteal phase of the menstrual cycle and remain low during the early follicular phase. These gonadal steroids modulate the central neurotransmitter function of serotonin, dopamine, norepinephrine, and γ -aminobutyric acid and thus, as their levels vary across the menstrual cycle, may influence symptoms of irritability, anxiety, depression, and fatigue. For example, the progesterone metabolites allopregnanolone and pregnanolone may have anxiolytic properties through their barbiturate-like effect on γ -aminobutyric acid receptors, with decreased levels of these metabolites correlating with increased tension and anxiety.

Premenstrual asthma, or the worsening of asthma symptoms and pulmonary function in relation to menstruation, has been described in approximately one-third of women. A number of studies reported increases in asthma prior to menstruation and, to a lesser extent, during menstruation. Mirdal suggested a relationship among lowered resistance to stress, lowered resistance to infections, and increased bronchial hyperreactivity as background etiological factors for the occurrence of premenstrual asthma.

The premenstrual and menstrual phases of the menstrual cycle have been associated with an increased vulnerability to an exacerbation of psychiatric symptoms, as well as a peak in psychiatric admissions. Literature in this area is limited to case reports and small studies, which have found evidence of premenstrual exacerbation in schizophrenia, depression, bulimia nervosa, anxiety disorders, and substance abuse. For example, in a prospective study of 27 women with research diagnostic criteria for major, minor, or intermittent depression responding to treatment with imipramine or phenelzine, one-fourth of the women experienced premenstrual recurrence of symptoms of low mood, anhedonia, anxiety, increased appetite, and hypersomnia, which remitted

following menses. For some women, an increased consumption of alcohol and marijuana occurs premenstrually. A study of 14 women with alcohol dependence found an association between alcohol intake and severity of premenstrual symptoms. Similar findings were reported in a prospective study of 21 women with a history of regular marijuana use. Smoking frequency has also been shown to vary across the menstrual cycle, with approximately 70% of women reporting an increase in the 7–10 days before their menstrual period. Researchers postulate that reproductive hormones may influence psychiatric symptoms by direct effects on central neurotransmitter function, as well as by causing the serum concentrations of medication to vary across the menstrual cycle.

Consequences of Amenorrhea

The hypoestrogenism associated with secondary amenorrhea can have long-term effects, the most significant of which is osteoporosis. Osteoporosis results from an imbalance between bone formation and bone resorption. Rapid increases in bone density are seen during puberty, with peak bone density of the spine and hip occurring by age 20. Females ages 14–18 with amenorrhea, especially if associated with weight changes, anorexia, or excessive exercise, risk decreased bone mineral density compared with normally menstruating young women. Amenorrheic athletes, for instance, have a significantly reduced spinal bone mineral content compared with controls with normal menstrual cycles. The peak bone density of premenopausal women influences the onset of osteoporosis later in life; thus, as life expectancy increases, the potential morbidity from osteoporosis also increases.

Treatment Issues

Stress can have a profound impact on menstruation and reproduction, ranging from cycles of marginal quality to chronic anovulation. Although mediated through biological actions on the hypothalamus, GnRH, and the HPA axis, these effects are potentially reversible. In managing women with functional hypothalamic amenorrhea, the psychological, behavioral, and psychiatric variables that influence hypothalamic function must be considered. Although pharmacological interventions can supply appropriate sex steroid exposure, restore hormonal balance, or induce ovulation, hormonal treatments can prevent the recognition of important emotional, behavioral, or psychiatric symptoms. Many women with FHA may have a potentially reversible condition

that can be addressed with education, changes in lifestyle, psychotherapy, assistance in identifying and coping with stressors, or attention to a psychiatric condition. Cognitive-behavioral therapy, for instance, has been shown to result in the recovery of ovarian function for women with FHA who do not have a psychiatric disorder or engage in excessive exercise. Such interventions can help ameliorate the long-term consequences of stress and anovulation, as well as the health hazards associated with relative hypoestrogenism.

Finally, in evaluating a woman of reproductive age, the relationship between her symptoms and her menstrual cycle should be considered. Emotional symptoms can vary across the menstrual cycle because reproductive hormones can influence vulnerability to stress as well as mood changes and anxiety. With an awareness of these fluctuations, women may benefit from a greater sense of predictability and control over their symptoms. In addition, overmedication or undermedication with pharmacological agents can be avoided.

Glossary

<i>α-Adrenergic activity</i>	Reflecting activity of sympathetic nervous system receptors located in the vasculature; stimulation leads to constriction of the blood vessels.
<i>β1-Adrenergic activity</i>	Reflecting activity of sympathetic nervous system receptors located in the heart; stimulation leads to increases in heart rate and contraction of the heart muscle.
<i>Cardiac output</i>	Quantity of blood ejected from the heart in liters per minute.
<i>Endothelin-1</i>	Potent vasoconstrictor peptide released by vascular endothelial cells.
<i>Hemodynamic</i>	Pertaining to changes in blood flow reflecting changes in the underlying components of blood pressure, cardiac output, and total peripheral resistance.
<i>Left ventricular mass</i>	Size of the heart muscle of the left ventricle; enlargement of the left ventricle is a risk factor for cardiovascular morbidity and mortality.
<i>Nitric oxide</i>	Potent vasodilator substance released by vascular endothelial cells.
<i>Psychophysiological</i>	Pertaining to the study of physiological responses to psychological stimuli (e.g., stressors).
<i>Serotonin transporter gene Promoter polymorphism (5HTTLPR)</i>	A coding variant in the promoter of the human serotonin transporter gene which results in low transcriptional activity of this gene and is thought to be a genetic susceptibility factor for depression.
<i>Total peripheral resistance</i>	The resistance to blood flow in the systemic blood vessels.

Vagal tone

Index of parasympathetic nervous system influences on the cardiovascular system.

Introduction

Mental stress testing is typically used to examine the physiological effects of exposure to acute stressors, i.e., tasks, presented in the laboratory. Widely used as a research technique, mental stress testing is usually intended to distinguish groups with varying risk for cardiovascular diseases. To this end, mental stress testing functions as a provocative tool for unmasking information that is not available from assessments made under static conditions alone. As such, the psychophysiological adjustments that occur in the context of mental stress testing can enhance understanding of regulatory adjustments due to exposure to stress. Furthermore, these adjustments have implications for the reactivity hypothesis, which states that individuals who consistently display exaggerated cardiovascular responses (i.e., reactivity) to stressors may be at increased risk for the development of hypertension and/or coronary heart disease. The present discussion is limited to cardiovascular responses, although mental stressors also affect other systems such as those pertaining to neuroendocrine and immune function.

Conducting Mental Stress Testing

Baseline, Stress, and Recovery Periods

Mental stress testing requires assessment during resting baseline as well as during stress conditions. Regulatory mechanisms operative under resting conditions become modified as individuals are exposed to stressors. Examination under baseline conditions in the laboratory is requisite since it provides a comparison against which stressor-induced responses can be evaluated. Baseline measures may be affected by a variety of factors, including level of consciousness, habituation to the laboratory and procedures, time of day, posture, and prior substance ingestion (e.g., cardioactive agents such as caffeine, nicotine, and certain medications). As such, the baseline serves as a control level; a true basal level is not likely to be achieved under these circumstances. In relation to control levels, stressor-induced responses provide a sample of dynamic adjustments under varying conditions. In addition, recovery to baseline levels following the

termination of the stressor is often examined, as it provides further information about homeostatic mechanisms. To minimize extraneous influences and to ensure precise stimulus control, procedures for acquiring the baseline, stressor, and recovery data must be highly standardized. Efforts to enhance standardization have included scripted and/or taped instructions and computer presentation of stressor stimuli.

Types of Laboratory Stressors

Laboratory studies have utilized a wide range of stressors that differ to the extent that they elicit psychological versus physical stress. Social stressors include speech stressors (preparing and presenting a speech), interviews designed to elicit general or specific emotional responses, and tasks intended to mimic real-world social interactions, such as discussions of current events and role-play involving interpersonal conflict. Nonsocial psychological stressors include, but are not limited to, mental arithmetic (e.g., serial subtractions), mirror tracing (tracing a star looking only at its reflection in a mirror), reaction time (e.g., rapidly pressing a button in response to specific stimuli), the Stroop color-word interference test, video games, puzzle-solving tasks, and films (often consisting of graphic footage). Another commonly used stressor, the cold pressor test, is a physical stressor with a measurable psychological component. This task typically involves immersing a limb in ice water or placing an ice pack on the forehead. Finally, tasks such as static (e.g., squeezing a handgrip device) or dynamic (e.g., walking on a treadmill, riding a stationary bicycle) exercise are generally regarded as pure physical stressors and, thus, are not the focus of this article.

Several methods of classifying tasks have been proposed. A classic categorization scheme is Lacey's notion of sensory intake versus sensory rejection. Sensory intake tasks (e.g., reaction time) refer to stressors that require attention to visual or auditory cues in the external environment, while sensory rejection tasks (e.g., mental arithmetic) require mental work facilitated by blocking out external distractions. The most widely used classification system was proffered by Obrist, who distinguished laboratory stressors on the basis of the behavioral dimensions required for task completion, i.e., active versus passive coping. Active coping tasks provide an opportunity to influence the outcome of the situation by performing a specific behavior, while passive coping tasks require passive endurance of the stressor. Tasks such as shock avoidance reaction time, mental arithmetic, speech, video games, and the Stroop color-word interference test are considered active coping stressors. Examples of

passive coping tasks include the cold pressor test and film viewing.

Task Selection

Mental stress testing may involve presenting individuals with one or more laboratory stressors. It is recommended that task selection be guided by the specific questions that the research intends to address. For example, the research question would determine whether a stressor that elicits responses that are variable or uniform in magnitude is chosen. An explicit rationale for stressor choice also requires articulation. Selection decisions are often made on the basis of the behavioral demands associated with the stressors. To illustrate, an investigator may wish to compare responses to stressors involving active coping with those requiring passive coping. This would be particularly critical for studies comparing Black and White Americans. The literature indicates that Blacks, who as a group have a higher prevalence of hypertension than Whites, are more responsive to passive coping stressors, whereas Whites are more reactive to active coping stressors.

The relevance of stressors to the groups under study also requires consideration. Stressors, by virtue of the domains they tap, may hold differential relevance for one group relative to another. For example, a large body of research comparing males and females (children and adults) and employing cognitive and/or achievement-oriented stressors demonstrated that males show exaggerated physiological responses compared to females. Given the differential gender-related expectancies for performance that are likely in such situations, it is probable that those types of tasks may have been less relevant for the females. Therefore, it is essential to select stressors that are expected to be equally pertinent to participants.

When there is interest in the relationship between mental stress and a particular psychosocial variable, a fair test requires the inclusion of a task that is relevant to the specific construct. To illustrate, if one is interested in the relationship between trait anger and responses to mental stress, it is incumbent upon the investigator to include an anger-relevant task. This situation will provide an opportunity for individual differences to emerge.

Consideration also needs to be given to the response patterns evoked by the stressor when making stressor choices. Investigators often wish to compare stressors that elicit different hemodynamic responses. Such decisions are aided by the availability of noninvasive methods (e.g., impedance cardiography) to assess hemodynamic parameters such as cardiac output and total peripheral resistance during mental stress testing.

Task Differences in Responses to Mental Stressors

Research indicates that mental stressors evoke integrated response patterns across several parameters rather than an isolated response in a sole parameter. Consequently, a vast array of stressors elicits relatively few response patterns. Situational stereotypy, the propensity for a specific type of mental stressor to elicit a particular response pattern, is well known. Pattern 1 and Pattern 2 response patterns have been identified. Pattern 1 is characterized by skeletal muscle vasodilation, elevated heart rate, augmentation of blood pressure primarily as a function of increases in cardiac output, enhanced β 1-adrenergic activity, and decreased vagal tone. This myocardial response pattern is thought to characterize mental stressors involving active coping, sensory rejection, or mental work. Pattern 2 is associated with skeletal muscle vasoconstriction, smaller changes in heart rate, increases in blood pressure largely due to augmented total peripheral resistance, heightened α -adrenergic activity, and increased vagal tone. Stressors thought to elicit this vascular response pattern include those that involve passive coping, passive avoidance, inhibition, sensory intake, and vigilance. The use of adrenergic pharmacologic blockade has been informative with respect to clarifying the degree to which mental stressor response patterns are mediated by β -adrenergic and α -adrenergic receptor activity.

While Pattern 1 and Pattern 2 responses are often associated with active and passive coping stressors, respectively, some active coping tasks such as certain versions of mental arithmetic and speech (i.e., presentation period, not preparation) stressors are often associated with more of a mixed response pattern, composed of myocardial and vascular responses. It is well known that several variables influence and alter hemodynamic response patterns. A Pattern 1 response can be modified by a variety of factors, including instructional sets, expectations, appraisals, controllability, incentives, effort, predictability, individual differences, and the like, resulting in mixed response patterns.

Individual Differences in Responses to Mental Stressors

Responder Types

In addition to situational stereotypy, response stereotypy, which reflects the propensity for an individual to display a consistent response pattern across stressors, is also operative. A promising approach to the investigation of individual differences in reactivity to

stressors has been the identification of participants on the basis of their response patterns. The literature shows that some individuals respond in a consistent hemodynamic manner across active coping and passive coping mental stressors. In this regard, among men, Black Americans are more prevalent among vascular responders, whereas White Americans are more prevalent among myocardial responders across various stressors. Alternatively, evidence also supports the view that individuals may respond in a variable manner across myocardial and vascular dimensions to specific stressors. It should be noted, however, that for certain stressors, due to their stimulus characteristics, situational stereotypy might overwhelm the response stereotypy of the individual. For example, the cold pressor test typically elicits a Pattern 2 response pattern despite an individual's response stereotypy. Nonetheless, there is considerable individual variability with respect to how that stressor is tolerated and experienced.

Psychosocial Variables

The literature linking psychosocial variables to individual differences in cardiovascular reactivity assumes that when confronted with a stressor, individuals possessing certain psychosocial characteristics display exaggerated cardiovascular responses. The most commonly studied constructs include Type A behavior pattern and hostility/anger. A meta-analysis of the Type A reactivity literature concluded that Type A males, but not females, exhibit greater heart rate and systolic blood pressure reactivity to a variety of tasks than their Type B counterparts. These findings were dependent upon the type of task used, and the strength of findings varied with the method of Type A behavior pattern assessment (i.e., interview or questionnaire). Numerous studies have examined relationships among hostility and/or anger and cardiovascular reactivity. Qualitative and quantitative reviews of this literature conclude that hostility/anger is consistently related to reactivity to social/interpersonal stressors (e.g., involving provocation) but not to reactivity to standard nonsocial stressors.

Other Considerations

Prolonged Recovery

There is growing support for the notion that prolonged recovery has pathophysiological consequences. Evidence of delayed blood pressure recovery is available for hypertensives, as well as for groups at risk for future hypertension, such as borderline hypertensives, Blacks, and individuals with a family history

of hypertension. Furthermore, prolonged recovery from mental stress in borderline hypertensives has been shown to predict future sustained hypertension. Several recent studies have provided evidence of concurrent and prospective associations between recovery and outcome measures in adults and adolescents. Overall, research indicates that blood pressure and/or heart rate recovery may contribute uniquely to the prediction of ambulatory or resting cardiovascular measures.

Given increased recognition of the importance of recovery, investigation of the psychosocial correlates of post stressor responses is of interest. While a number of psychosocial factors have been examined in this regard, a promising variable is post stressor rumination, particularly when it involves the experience of anger. Studies have demonstrated delayed recovery from tasks involving harassment relative to nonharassment conditions, as well as more rapid recovery when participants are distracted and, thus, prevented from ruminating following emotionally provocative tasks.

Individual-Task Interactions

Understanding the potency of the mental stressor requires considering the interaction of the individual with the mental stressor. Although it is assumed that the stressor is perceived as stressful by the participants, in practice, this may not be the case. Appraisal of the stressor may be influenced by several situational variables, including the social context of the experiment, task ease, controllability, and novelty. In addition, subject variables such as experience, ability, involvement, and fatigue are also likely to impact perceptions. The individual's preexisting attitudes toward, experience with, and ability to perform similar tasks in real-life situations may also influence perception of the stressor. Stressor appraisal consequently will affect the extent to which the individual is engaged by the stressor. Engagement and involvement with the stressor are key in determining its efficacy and may reciprocally influence the effort that the individual expends when confronted with the stressor.

Stability

The notion that cardiovascular responses to mental stressors are relatively stable across tasks and over time is a critical assumption of the reactivity hypothesis. To make the case that exaggerated stress-induced responses have a detrimental impact on the cardiovascular system, it is first necessary to demonstrate that reactivity is a reproducible phenomenon. With regard to the stability of reactivity, there is increasing

evidence of adequate test-retest reliability for cardiovascular responses to laboratory stressors, particularly with task standardization, presentation of alternate forms of the stressor, aggregation of responses across tasks and testing sessions, and relatively short test-retest intervals. Furthermore, meta-analytic reviews report stability of responses over periods of years in adult and pediatric-aged samples.

The adequate evaluation of the health implications of recovery also requires reliable recovery measures. Research shows that the test-retest reliability of recovery using definitions, such as the time required to return to baseline levels following stressor termination, does not yield adequate test-retest reliabilities. Other findings suggest that the reliability of recovery scores might be improved by aggregating measures across tasks. Future research needs to be directed at identifying factors that affect long-term stability of both reactivity and recovery.

Laboratory-to-Field Generalization

A second implicit assumption of the reactivity hypothesis is that an individual's cardiovascular responses to laboratory stressors are representative of responses to stressors encountered in everyday life. Evidence for the laboratory-to-field generalizability of reactivity remains marginal. Critics maintain that generalizability is adversely affected by the failure to utilize ecologically valid tasks in mental stress testing protocols. Given the lack of accepted standards to demonstrate that a stressor is ecologically valid, the ecological validity of a stressor is typically based on face validity rather than on psychometric characteristics. For example, it has been suggested that the use of interpersonal or social stressors might improve generalization, as real-life stressors are likely to involve social factors; the data on this issue remain mixed. Future research needs to be directed at specifying the properties that determine a stressor's ecological validity. When making choices about whether a laboratory stressor should be used as a predictor, it is likely that the investigator would be best served by selecting a task that elicits stable cardiovascular responses over the long term. Given the chronicity of naturally occurring stressors, predictability might be enhanced when prolonged laboratory stressors, rather than the typically brief stressors, are employed.

Left Ventricular Mass

While definitive support for the reactivity hypothesis would require demonstrating an association for cardiovascular reactivity and the development of hypertension and/or coronary heart disease, establishing a

relationship with proximal medical endpoints would support the validity of the reactivity construct. The use of proximal endpoints, however, would not obviate the need for definitive longitudinal studies, which are not without their own limitations. Nonetheless, increasing attention needs to be directed at examining the association of cardiovascular reactivity evoked by mental stressors and proximal endpoints, such as increased left ventricular mass, a potent predictor of coronary heart disease. To date, the literature suggests that the relationship is modest at best. Further research examining this association is warranted, particularly as it pertains to left ventricular modeling and the contributions of responder type, ethnicity, and gender.

Genetic Contributions

The potential contributions of heritable factors to individual differences in cardiovascular reactivity have long been recognized. It has recently been proposed that future studies should involve systematic consideration of genetic, as well as environmental, factors as moderators or mediators of the association between reactivity and health outcomes. Technological advances are enabling the exploration of the role of specific genes in the determination of individual differences in reactivity. Some of the more promising candidates include, but are not limited to, the adrenergic receptor genes (i.e., β_1 , β_2 , α_1 , and α_2), the endothelin-1 and endothelin-1 receptor A genes, nitric oxide synthase genes, and the serotonin transporter polymorphism, i.e., 5HTTLPR. For instance, a few studies have demonstrated associations of polymorphisms of the β_1 - and β_2 -adrenergic receptor genes with blood pressure reactivity and/or resting or stress levels. Similarly, the 5HTTLPR polymorphism has been associated with greater heart rate and/or blood pressure responses. There is, however, conflicting evidence regarding whether greater reactivity is observed in individuals with one or two long 5HTTLPR alleles or in individuals with two short alleles, as well as whether such relationships are moderated by gender.

Conclusion

Mental stress testing typically involves the assessment of physiological responses in a laboratory setting during exposure to mental stressors and baseline and recovery conditions. Stressors range from psychological to physical and social to nonsocial. Stressors differ in the behavioral demands required of participants. Tasks also elicit certain well-defined physiological response patterns. Researchers should employ

stressors that most effectively address their research questions, taking into consideration the appropriateness of behavioral task demands, the significance of tasks for the groups being studied, and the relevance of tasks to psychosocial variables or response patterns of interest.

With few exceptions, there may be considerable individual variability in responses to mental stressors. Sources of variability include individual differences in the propensity to exhibit a particular response pattern, psychosocial characteristics, and a variety of preexisting and situational factors influencing individual-task interactions. In conducting mental stress testing, a number of additional areas of inquiry are worthy of consideration. These include the reproducibility of responses across stressors and testing sessions, the generalizability of laboratory responses to field settings, the predictability of proximal medical endpoints, and genetic contributions.

What Is Metabolic Syndrome?

Origins of MetS

MetS and Environmental Stress

Development of MetS in Childhood

MetS and Inherited Temperament

Glossary

<i>Innate temperament</i>	A biologically rooted behavioral disposition that is stable across time and situations.
<i>Metabolic syndrome (MetS)</i>	A constellation of physiological and metabolic abnormalities.

What Is Metabolic Syndrome?

Metabolic syndrome (MetS), also called insulin resistance syndrome, is a cluster of various physiological and metabolic abnormalities including hyperinsulinemia, hyperglycemia, hypertension, a decreased plasma concentration of high-density lipoprotein (HDL) cholesterol, an increased plasma concentration of very low density lipoprotein (VLDL) triglyceride, glucose intolerance, and abdominal obesity. Insulin resistance is the primary metabolic defect of this syndrome, with compensatory hyperinsulinemia being the common denominator ultimately responsible for other changes of this constellation. In addition to insulin resistance, abdominal obesity is a key contributor to the development of MetS (see **Figure 1**).

MetS is a huge public health problem worldwide that is responsible for a growing number of premature deaths throughout the world. Its prevalence is

approximately 16% among Caucasians. However, comparison across different countries is difficult as there are different age structures of the population, and even though a World Health Organization (WHO) expert committee published a definition of MetS, there are other, differing definitions available.

MetS is significant because it plays an important role in the etiology of coronary heart disease (CHD) and non-insulin-dependent diabetes mellitus (type II diabetes). Type II diabetes is one of the most prevalent and serious metabolic diseases in the world, and among middle-aged men, CHD is still the leading cause of mortality in Western countries.

Origins of MetS

The exact cause of MetS is not known. It is generally accepted that a genetic predisposition, possibly an interaction of several genes, is an essential factor in the genesis of this disorder. In addition to a genetic predisposition, lifestyle factors such as physical inactivity, habitual alcohol drinking, and smoking play a role in the development of MetS. There is also compelling evidence that stress of diverse origins has a significant role in the development of MetS. It is well established that the development of MetS is indisputably related to activity and/or dysregulation in the two major physiological and neuroendocrine stress systems, the sympathetic-adrenomedullary (SA) system and the hypothalamic-pituitary-adrenomedullary (HPA) system, a key component being the activation of the HPA axis.

The primary role of SA and HPA systems is increasing the energy available for action; activity of these systems is needed in everyday performance. The label of stress systems is based on the fact that they are very sensitive to physical and mental stress. Stress usually refers to overactivity or dysregulation of those systems, not to their ordinary functioning.

Figure 1 Contributing factors of metabolic syndrome.

Figure 2 Stress contributes to the development of diabetes and coronary heart disease through metabolic syndrome.

SA and HPA systems are both known to exert marked insulin resistance. This is especially true with responses of serum cortisol, as it regulates glucose levels in the blood, with all of the accompanying consequences. To summarize, mental stress might contribute to the development of MetS and subsequently increase the risk of CHD and diabetes via the SA and HPA axes, with increased cortisol secretion being of basic importance (see [Figure 2](#)).

MetS and Environmental Stress

Evidence of the contribution of environmental stress to MetS via increased reactivity of the stress axis was first derived from animal experiments. It was shown that in standardized experimental stress situations, macaque monkeys reacted with helplessness and loss of control (i.e., with a behavioral stress reaction) and responded with an increased level of cortisol and detached MetS symptoms, especially body fat. Comparable findings have been reported with rats exposed to chronic, uncontrollable environmental stress.

In line with animal studies, it was shown in laboratory experiments with human beings that persons with a high level of MetS symptoms were likely to express elevated responses of serum cortisol during task-induced mental stress.

Research has predominantly emphasized the role of the HPA axis when searching for the mechanism mediating the relationship between stress and MetS. Enhanced sympathetic activity (SA activity) is, however, important as well because chronic sympathetic overactivity with hemodynamic consequences (increased heart rate and pulse pressure) may have pathogenic importance in the development of MetS.

It is also known that long-lasting stress predisposes a person to stronger acute stress reactions, both mental and physical; that is, chronically stressed individuals are likely to show greater reactivity to and prolonged recovery from short-term challenging tasks.

Evidence of the influence of stress on MetS has mostly been based on laboratory experiments, whereas real-life situations, that is, the influence of everyday mental stress, especially long-lasting stress, have not been well studied. The risk characteristic that has been systematically shown to be related to both reactivity of the HPA axis and MetS is vital exhaustion. Vital exhaustion is seen as an indicator of long-lasting mental stress and is characterized by feelings of excessive fatigue, loss of energy, increased irritability, and demoralization. It is also well established that vital exhaustion is a risk factor for CHD, especially for myocardial infarction. The highest risk here, however, is not related to a high level of cortisol but to

hypocortisolemia, a state in which both mental and physiological reservoirs are unavailable. This questions the common argument that high risk would be related to high cortisol secretion.

We also know that several coronary-prone personality characteristics, such as type A behavior (i.e., a behavior pattern consisting of aggression, impatience, high striving for achievement, ambitiousness, competitiveness), hostility, and anger, are related to perceived stress and reactivity of SA and the HPA axis. They are also related to components of MetS, even though the empirical findings have not been consistent.

If environmental stress is likely to increase the level of MetS, there is also an inverse effect: environmental support is able to decrease the level of MetS. It is known that changes in perceived social support are associated inversely with changes in the MetS level; that is, increasing support decreases the level of MetS and vice versa. The effect of social support in stress and diseases is widely documented. It increases the overall positive effect, feelings of self-worth and acceptance. It may exert stress-buffering effects by affecting the appraisal of potential stressors or by bolstering coping efforts.

Development of MetS in Childhood

It is generally accepted that atherosclerosis, the underlying process of CHD, originates in childhood and adolescence and that CHD risk factors are already present then. In addition, fasting insulin levels in early adolescence have been shown to predict type II diabetes in young adulthood.

The MetS precursors also appear to be present as early as childhood. It has been shown that the essential parameters of MetS express strong clustering and high tracking, even in healthy children and

adolescents. Consequently, the potential effect of stress on the parameters of MetS even in childhood and adolescence has evoked interest. Until recently, the studies were few in number. There are, however, findings that suggest that a stress-prone and inappropriate childhood environment predisposes a child to a high level and early tracking of the parameters of MetS. Sources of environmental childhood stress are, of course, likely to stem from the family environment, especially from parental child-rearing practices. It is well established that a mother's hostile child rearing, consisting of a strict disciplinary style, a tendency to emotionally reject the child, and a feeling that the child is a burden on her, preventing her self-fulfillment, indicates an environmental stress that, in some studies, has been shown to be correlated with an elevated level of a child's MetS parameters.

With regard to the child's own characteristics, some components of type A behavior in adolescence predict changes in the level of MetS, with aggressive competitiveness being especially associated with an increase of that syndrome. In addition, some findings suggest that childhood temperament, especially hyperactivity and negative emotionality, is associated with and predict a later elevated level of MetS (see [Figure 3](#)).

MetS and Inherited Temperament

The findings previously described are related to the question of whether inherited temperament could play a role as a stress buffer or make a person vulnerable to stress and consequently explain a variance of MetS. Temperament refers to biologically rooted individual differences in behavioral reactions and dispositions that are present early in life and are relatively stable across time and situations. Temperament

Figure 3 Origins of metabolic syndrome.

is an inherited core of personality; personality is developed by the interaction of inherited temperament and environment, mostly parental child-rearing practices.

Temperament has its origins in brain structures, and individual differences in temperament reflect innate differences in neuroendocrine and autonomic nervous system functions. Therefore, a biologically determined temperament has been viewed as one of the sources responsible for individual differences in stress proneness. It has been suggested to explain the variance in events that are experienced as stressful, and especially why daily troubles have greater health consequences for some individuals than others. There is, indeed, increasing evidence that differences in SA and HPA systems, i.e., differences in major stress systems, are attributable to different temperament profiles.

Findings suggest that childhood temperament plays a direct and indirect role in a development of MetS; that is, it interacts with the environment, meaning that some childhood temperamental factors (e.g., hyperactivity and negative emotionality) are related to an adulthood risk for MetS. In addition, childhood temperament also has an indirect effect. It has been suggested that the influence of hostile maternal child-rearing practices on the child's MetS level may be mediated by the child's temperament. Children with a difficult temperament, conceptualized in terms of negative emotionality (aggression and anger proneness), high activity, and low sociability, are especially vulnerable. Children with this type of temperament are especially prone to high levels of MetS when faced with hostile child rearing.

Interest in the role of adulthood temperament in individual stress reactions has been increasing of late. Findings have conflicted slightly with previous opinions on risk personality. A coronary-prone personality has traditionally been described in terms of hostility, depression, social aloneness, and type A behavior. In contrast, risk temperament is not primarily related to these kind of features; the most vulnerable individuals (i.e., persons who expressed systematically high levels of MetS) are those dealing with oversocialization and overresponsibility. These persons are highly sensitive to social cues of approval or the praise of others, have a strong tendency to conform to peer pressures, and are sensitive to the rejection of others, leading to excessive reward-seeking behaviors such as overworking in response to social rejection or frustration. As workers, they are persistent overachievers who frequently push themselves to exhaustion.

Issues concerning the role of temperament in physiological and neuroendocrine stress reactivity are still

new and thus in process. The findings, however, have been promising for explaining the complicated relationship between mental stress and MetS. The findings also suggest that psychological and physiological stress symptoms might have the same source – it may be possible in the future to find a solid neurobiological basis for both psychological and physiological stress reactions.

The Impact of Stress in Animal Studies

Effects of Stress in Humans

The Physiology of Stress

The Long-Term Effect of Stress on the Human Body

Concluding Remarks

Glossary

<i>Metabolic syndrome</i>	A well defined group of metabolic risk factors such as insulin resistance, atherogenic dyslipidemia, central (abdominal) obesity and hypertension.
<i>Hypothalamic-pituitary-adrenal axis</i>	The hormonostatic endocrine axis that regulates cortisol production and secretion.
<i>Sympathetic nervous system</i>	A division of the autonomic nervous system which mediates the response of the body to stress.

In recent years, scientists have recognized that some risk factors for cardiovascular disease and type 2 diabetes cluster together in certain people. The causal risk factors involved in the significant increase in cardiovascular disease and type 2 diabetes stem mostly from a now well-defined group of multiple metabolic risk factors called the metabolic syndrome (MetS). These risk factors include elevated insulin levels (insulin resistance), central (abdominal) obesity, atherogenic dyslipidemia, and hypertension. While these combined risk factors do not usually cause overt disease symptoms, it is obvious that persons with at least several of these correlated factors

greatly increase the likelihood of atherosclerosis, heart disease, stroke, diabetes, kidney disease, and ultimately even premature death. Complicated genetic factors such as race, age, family weight, and diabetes history that interact equally with complicated cultural, dietary, psychosocial stress, exercise, and smoking factors, result in a heterogeneous at-risk patient group yet surprisingly consistent poor prognosis.

As MetS is gaining wider recognition in the clinic as a serious life-threatening condition, researchers and doctors are struggling to formalize the connections among all the diverse symptoms, risk factors, and correlated conditions. Of all the factors influencing MetS, chronic psychosocial stress is likely the most pervasive and controllable. Stress has long been recognized as a major contributor to hypertension, endocrine dysfunction, diabetes, and elevated cortisol-related conditions such as gluconeogenesis, increased serum glucose levels, decreased insulin production, perpetuation of catecholamine vasoconstriction, increased arterial blood pressure, fat and protein mobilization, and centralization of body fat. Considering the overlap in symptomatology between stress-correlated conditions and MetS, connecting the two, at least heuristically, is not a stretch. Indeed, solid evidence now exists that suggests the two conditions have reciprocal effects, with chronic stress including MetS and increased intra-abdominal fat and other hormonal dysfunction augmenting cortisol-induced stress and somatopsychic effects.

The Impact of Stress in Animal Studies

The activity of the hypothalamic-pituitary-adrenal (HPA) axis has been studied in several animal species in a variety of models of psychosocial stress. Not surprisingly, the majority of studies indicate that the HPA axis is activated in low-ranking animals in hierarchical social groups and in animals that have been defeated by a conspecific. However, activity and reactivity of the HPA axis has been shown

to be modulated by a variety of different factors, including the species, gender, and behavioral style of the individuals.

Socially subordinated animals are generally more reactive to a novel stressor compared to their dominant counterparts, as shown in social groups of mice, rats, hamsters, guinea pigs, squirrel monkeys, and olive baboons. Taken together, these data indicate that social subordination and defeat appear to be stressful and lead to HPA axis activation. Chronic social stress can lead to long-term changes in HPA axis activity, including persistent elevations in basal glucocorticoids, abnormal responses to subsequent stressors, and impaired feedback regulation. For the most part, these effects are seen most clearly in subordinated animals housed in stable social groups; however, similar responses have been observed in dominant animals in such groups, and also in animals of all ranks in unstable social grouping.

Effects of Stress in Humans

Social stress is generally viewed as a major factor in the etiology of a variety of psychopathologies such as depression and anxiety, in addition to its effects on male and female reproduction, immune functioning, heart disease, etc. Social stress in people is often evaluated in terms of the number and magnitude of life events that an individual experience, and a general conclusion from this approach is that a plethora of moderately stressful events can have as great an impact as a few major events. Another important index that is strongly associated with the number of stressful events that are likely to be experienced is social status. Low social status is regarded as having an impact on almost every area of the individual's life. Furthermore, the ranking difference itself, and the meaning assigned by the individual to his or her status with reference to others, may provide stress that is additional to (or interactive with) the material consequences of low status.

The Physiology of Stress

The stress response occurs through two major pathways in the human body: the central nervous system (CNS) and the endocrine system. The sympathetic nervous system (SNS) of the CNS that is involved when a stressor is encountered is the SNS stimulation of the adrenal glands, which, releases the catecholamines epinephrine (adrenaline) and norepinephrine (noradrenaline). The resulting fight-or-flight response via catecholamine release from end target neurons has an immediate effect by increasing heart rate, force of

myocardial contraction and cardiac output, arterial blood pressure, blood coagulation, and serum glucose.

Simultaneously with nervous system stimulation, the hypothalamus and the pituitary glands secrete hormones into the general circulatory system. Once in the bloodstream, they arrive at the adrenal glands, which then secrete glucocorticoids, mainly cortisol, into the bloodstream to assist meeting the demands of the stressors. This endocrine pathway of hormones increases body metabolism, increases fatty acids in blood, increases blood pressure, and retains extra sodium, which results in increased water retention.

The Long-Term Effect of Stress on the Human Body

Since the early 1980s, a wealth of information has accumulated which illustrates that activation of the HPA axis leads to suppression of both the growth axis and the reproductive axis including activation of the sympathetic system. Chronic increase in cortisol, catecholamines, and chronic suppression of the growth and reproductive axes leads to a number of adverse health effects, and their sequelae result in increased morbidity and mortality.

Cortisol interferes at several levels of insulin action. In addition, cortisol inhibits insulin secretion from pancreatic β -cells. In primary cultured adipocytes, synthetic glucocorticoids (dexamethasone) induce progressive insulin resistance by sequentially regulating multiple aspects of the insulin-responsive glucose transport system. In the early stages, dexamethasone impairs the ability of insulin to translocate intracellular glucose transporters (GLUT 4) to the cell surface. Some, but not all, studies indicate that glucocorticoids may increase hepatic glucose metabolism. This diabetogenic effect of glucocorticoids is well characterized at least in animal models. In skeletal muscle, cortisol inhibits the glycogen synthase. Recent data indicate that subjects with insulin resistance do have an increased number of glucocorticoid receptors (GRs) in muscle.

In summary, initially hyperglycemia is accompanied by an increased insulin response to a glucose load, but eventually β -cell response becomes insufficient, and the unopposed actions of stress-related counterregulatory catabolic hormones (cortisol, catecholamines) serve to exacerbate the metabolic disturbances and contribute to the biochemical changes seen. This simplified account provides a framework within which the association between stress and insulin resistance can be understood.

Cortisol regulates adipose-tissue differentiation, function, and distribution, and in excess, causes

visceral obesity. Glucocorticoids exert their cellular action by complexing with a specific cytoplasmic GR, which in turn translocates to the nucleus and binds to specific sites on chromatin. GRs belong to the superfamily of nuclear transcription factors. Cortisol exerts chronic effects on lipid metabolism. One of the most striking effects in humans is the centralization of body fat seen in Cushing syndrome, exhibited as severe truncal obesity. Excess cortisol promotes the activity of lipoprotein lipase (LPL), the primary enzyme responsible for conversion of lipoprotein triglyceride into free fatty acids and accumulation of triglycerides in adipocytes. The density of GRs, assessed by ligand-binding techniques and hybridization techniques with GR cRNA probes, is particularly high in intra-abdominal adipose tissue as compared to other regions. Furthermore, the antilipolytic action of insulin during the prevailing hyperinsulinemic state causes a blunted lipid mobilization, resulting in a condition with increased lipid accumulation. Moreover, in the presence of insulin, cortisol has a marked stimulatory effect on LPL activity in human adipose tissue *in vitro*. This effect involves both an increased level of LPL mRNA, leading to increased relative LPL synthesis, and additional posttranslational regulation.

The primary reason for considering stress as an etiologic factor relates to the influence of the SNS and neuroendocrine factors in hypertension, although high salt intake in some subjects may contribute through volume expansion. The principal hypothesis is that the stress-induced activation of hypothalamic, sympathohormonal regions occurs repeatedly over time, leading to cardiovascular adjustments that increase hypertension risk. Evidence relevant to this hypothesis derives from both animal and human experimental studies. Complications such as myocardial infarction and stroke are not directly due to elevated pressures, but to the resulting structural changes in the heart and blood vessels. One of the structural consequences of hypertension, hypertrophy of the left ventricle, is the strongest predictor, other than advancing age, of cardiovascular morbidity and mortality.

Concluding Remarks

The human body has many effector systems including the SNS and the HPA axis for maintaining homeostasis and connecting the brain with the periphery. Overall these systems interact both indirectly and

directly. The HPA axis determines most of the acute and prolonged effects of stressors. The secretory end product of the HPA axis, cortisol, is kept within an optimal range through the feedback action of cortisol interacting with neural control mechanisms. Distressing events or situations evokes these two pathways of the stress response. However, each person's unique combination of heredity, life experience, personality, and ability to cope are all involved in the perception of an event and the meaning attached to it. Rather than confronting life-threatening stressors, life today centers around events that hold symbolic meaning; an upcoming test, a disagreement with a friend, or the boredom of a job.

Individuals with persistent psychosocial and socioeconomic handicaps such as anxiety and depression, poor economy, low education, and unemployment are more likely to suffer from frequent challenges of the SNS and the HPA axis. Thus, psychosocial stress preceded by genetic susceptibility that result in a disruption of central regulatory systems all adds up to less coping ability, followed by insulin resistance, atherogenic dyslipidemia, central (abdominal) obesity, and hypertension, that is, the metabolic syndrome.

Introduction

Biometals in the Developing Organism

Biometals in the Adult

Parkinson's Disease

Alzheimer's Disease

Glossary

Alzheimer's disease (AD)

A progressive form of dementia with symptoms that include impaired memory, usually followed by impaired thought and speech. AD is histologically characterized by the deposition of extracellular amyloid plaques, the major constituent being the amyloid- β peptide (A- β).

Biometals

Metals found in living organisms that have defined physiological functions that serve to maintain normal cellular processes. These include copper (Cu), zinc (Zn), iron (Fe), and manganese (Mn).

Dopamine (DA)

A neurotransmitter that normally acts to reinforce behavior. Drugs of addiction act by causing dopamine release; a lack of dopamine results in the symptoms of Parkinson's disease. L-Dopa treatment provides the precursor for DA that partially compensates for the reduction of DA observed in Parkinson's disease.

Oxidative stress

The damage to cells caused by reactive oxygen species (ROS; e.g., hydrogen peroxide). Metals such as iron and copper are capable of redox chemistry in which a single electron may be accepted or donated by the metal, reacting with oxygen and thereby producing radicals and ROS. Oxidative stress is imposed on cells as a result of an increase in oxidant generation, a decrease in antioxidant protection, or a breakdown in oxidative damage-repair mechanisms.

Parkinson's disease (PD)

A debilitating disease occurring only in humans and resulting from a predominant loss of dopamine neurons. The symptoms include muscle rigidity, tremor, slow and shuffling gait, masklike facial expressions, and eventually cognitive decline and death. Some neurons

Reactive oxygen species (ROS)

contain Lewy bodies that consist of intracellular inclusions of α -synuclein.

Natural by-products of the normal metabolism of oxygen that have important roles in cell signaling. During times of biological stress, ROS levels can increase, resulting in significant damage to, or death of neurons.

Substantia nigra (SN)

A specific part of the brain that is made up of neurons that contain the chemical neurotransmitter dopamine; loss of these cells occurs in Parkinson's disease.

Toxicological metals

Metals with no known normal biological function; these include lead and aluminum. These metals can interact with many proteins, resulting in the dysfunction of many biological processes.

Introduction

The brain is an exceptional tissue in that it concentrates biometals (copper, zinc, iron, and manganese) for its normal functional metabolism. Some of these processes include maintaining enzymatic and mitochondrial function, immunity, myelination, learning and memory, co-release with neurotransmitters, and binding with prion proteins. The importance of metals in antioxidant defense mechanisms should also be highlighted; for example, Cu/Zn superoxide dismutase protects against oxidative stress. The concentration of biometals in the brain, together with the brain's high levels of oxygen, appears to make the central nervous system vulnerable to a host of metal-centered pathologies.

Biometals in the Developing Organism

Deficiencies in biometals result in increased mortality, abnormal development, and poor growth. The accumulation of iron in the brain appears to be handled differently than the other biometals. Whereas copper, zinc, and manganese can be absorbed by the brain after the organ has developed, the neonatal period is critical for the establishment of normal iron content in the adult brain. Iron accumulates in the brain only while it is still growing; for rats and mice this occurs in the first few postnatal weeks, whereas in humans the period begins during the third trimester of pregnancy and is maintained throughout the first year of life. Iron, copper, zinc, and manganese are found in the milk of humans and other mammals. Mammalian milk meets the crucial

supply requirements needed for the normal development of the neonate, with these biometals varying in concentration during the course of lactation. Interestingly, the iron content of milk is not reduced even when the iron status of the mother is poor, indicating tight regulation of the iron content of milk. Toxic milk syndromes have been observed in mice that have genetic defects in the copper or zinc pathways resulting in the abnormal delivery of these biometals, with significant biological consequences. Deliberately increasing the exposure of neonates to iron in this critical period has been shown to elevate iron levels in the adult brain.

Biometals in the Adult

Early studies used the term “trace element” to designate elements that are essential for normal function, including zinc, manganese, copper, iodine, iron, cobalt, molybdenum, tin, selenium, and chromium. The minimum nutritional requirements for individuals are hotly debated in the popular and scientific literature and are not discussed here. What is clear is that various genetic mutations can cause a disruption in the homeostasis of these elements, resulting in dramatic biological consequences (e.g., Segawa’s syndrome and iron; Wilson’s disease and copper). Biometals normally bind to a range of specific proteins (e.g., Cu/Zn and Mn bind to superoxide dismutase; Cu binds to the prion protein). Poisoning occurs when the levels of biometals exceed the body’s capacity to bind them to specific metal-binding proteins. Two outcomes likely to result from this are that (1) the metal binds to an incorrect protein, causing dysfunction in a biological system or (2) the presence of such metals in an unbound form causes oxidative stress, which damages cells.

Parkinson’s Disease

Parkinson’s disease (PD) is characterized by the loss of dopaminergic neurons of the substantia nigra (SN) and the deposition of intracellular inclusion bodies. The principal component of these deposits is the α -synuclein protein that is expressed throughout the brain, and mutations in this protein (A30P and A53T) are responsible for familial forms of the disease. The association between iron and PD is multifaceted and complex; too little iron leads to neurological deficits, yet too much appears to result in neuronal loss. There is long-standing evidence of a selective increase in iron in the SN of patients with PD as well as an accumulation in animals following artificially induced lesions to the SN. Iron is required for the synthesis of dopamine (DA): tyrosine hydroxylase, a nonheme

iron-containing enzyme uses molecular oxygen to hydroxylate tyrosine, resulting in the formation of L-Dopa, the natural biochemical precursor of DA and the most common medication for the treatment of PD. Mutations in the iron-binding site of tyrosine hydroxylase have been identified in cases of L-dopa-responsive PD and Segawa’s syndrome (a rare hereditary progressive dystonia with diurnal fluctuation). Other redox-active metals such as manganese have been associated with neurological disorders. Among the neurological effects of manganese poisoning (linked to occupational exposure) is an irreversible Parkinsonian-like syndrome. The specific mechanisms of the toxicity are not known.

Redox-active iron, α -synuclein, and DA are abundant in the SN. The three elements colocalized at one anatomical location can interact to generate toxic reactive oxygen species (ROS). It is apparent, however, that none of these elements alone is sufficient to perpetuate the neurodegeneration of PD: rather, the combination of iron, α -synuclein, and DA together generates toxic products. For instance, DA is a potent chelator of transition metals and can generate hydrogen peroxide in the presence of iron (or copper) and α -synuclein. Under these conditions, α -synuclein molecules link to form soluble aggregates known as oligomers. These oligomers are thought to be deposited as the microscopically visible intracellular inclusion bodies called Lewy bodies. This pathological mechanism has parallels with Alzheimer’s disease, in which current theory suggests that soluble oligomeric intermediates, rather than the visible aggregates (plaques), are the cause of neurodegeneration.

Alzheimer’s Disease

Alzheimer’s disease (AD) is characterized by the deposition of extracellular amyloid plaques, the major constituent being the amyloid- β protein (A- β) that is cleaved from the membrane-bound amyloid precursor protein. There is considerable evidence for an imbalance in the homeostasis of biometals in AD, which is reflected by specific alterations in metal levels in the brain (in areas such as the hippocampus, amygdala, neocortex, and olfactory bulb). These observations take into account the varying background of biometals that exists throughout life. Not only do the levels of biometals change with age, but so do the concentrations of different metal transport and storage proteins. Whereas metal levels in the brains of laboratory mice rise dramatically with age, studies of brain-metal content in aging humans are less conclusive. Interestingly, of the major biometals only zinc appears to be elevated in tissue from the

human AD brain. However, copper, zinc, and iron are present in very high concentrations, bound to the aggregated A- β that makes up the amyloid plaques. Although the normal function of A- β is unknown, it has been proposed that the biochemical environment of the aging brain provides conditions in which the A- β protein pathologically binds to copper and zinc, causing it to form oligomers that foster unregulated redox activity and toxic free-radical formation. A paradoxical consequence of the buildup of metals in the amyloid plaques is that the brain cells become deficient in these crucial biometal components, rendering them more susceptible to oxidative stress.

Physical Stress and Tumor Progression in Animals
 Psychological Stress and Tumor Progression in Animals
 Psychological Stress and Tumor Progression in Humans
 Modifiers of Tumor Progression
 Conclusion

Glossary

<i>Interferon</i>	Glycoproteins produced by cells infected with a virus which inhibit viral growth and may be useful to treat tumors.
<i>Metastasis</i>	The spread of malignant tumor to a distant site.
<i>Natural killer (NK) cell</i>	A white blood cell that can kill certain types of cancer cells.
<i>Prospective</i>	An experimental design which is forward-looking.
<i>Retrospective</i>	A design which looks back and reviews aspects of a clinical situation.

Rotational stress

Physical stressor whereby subject's cage is gently, but continuously, moved in a circle on a horizontal plain.

Tumor progression

A measure of the cancer's metastasis, size, and/or weight.

While there is ample evidence which suggests that stress can have immunomodulatory effects, prediction of disease outcome based on generalizations from studies which examine *in vitro* immune function is difficult since the direction and degree of immunomodulation has been shown to be dependent on both the stimulus parameters employed and the immune variables under study. Therefore, research has been directed at examining disease-specific outcomes such as the effects of stress on cancer. This article will provide a brief overview of the effect of stress on cancer by examining how a variety of physical and psychological factors can effect tumor progression in both animal subjects and human patients. Additionally, the article will suggest possible mechanisms for this phenomena by presenting several known modifiers of tumor progression (i.e., hormones and neurochemicals) that are relevant in a discussion of the physiological consequences of stress. While it is well beyond the scope of this article to fully review this

topic, several illustrative examples will be presented which were selected in order to demonstrate the complexity of this subject or because of their clinical relevance.

Physical Stress and Tumor Progression in Animals

Physical stressors are generally more easily defined than psychological stressors since they involve the imposition of a specific external condition or stimulus. It is important to be aware, however, that the imposition of these conditions will likely initiate a cascade of both physiological and psychological reactions to the stimulus.

There are a variety of physical stressors that have been shown to effect tumor growth in animal subjects including exposure to cold, changes in light/dark cycles, dietary restrictions, rotation, restraint, forced swim, and surgery. The complexity of the physiological and psychological cascade that follows the imposition of a rather simplistic physical stressor, such as rotation, is illustrated by a study by Zorz et al. (2002: 368). Similar to their findings with restraint stress, they found a circannual rhythm in the expression of metastasis with rotational stress increasing metastasis volume in June and decreasing it in February compared to controls. The antitumor agent cyclophosphamide was able to block metastasis in the control mice but not in the mice in the rotational stress condition. Furthermore, the survival time of control mice in February was twice as long as in June. In all groups, survival time was inversely correlated with number of metastases, and number of CD3+ and CD4+ splenic T lymphocytes. The authors suggested that T-lymphocyte-mediated immune responses that vary seasonally were modulated by the rotational stress.

Psychological Stress and Tumor Progression in Animals

Psychological stress models provide a mechanism for studying the effects of psychological phenomena on tumor progression and serve as potential models for the effects of stress and psychiatric illness on cancer since the physical components of the stressors are either minimal or appropriately controlled for. A variety of psychological stressors have been shown to be important modifiers of tumor progression including handling, inescapable shock, housing, and social dominance. An important test of the psychological component of a physiological reaction is whether or not the response can be conditioned.

For example, Wu et al. (2001: 1) examined the effects of social isolation on liver metastasis in mice. Metastasis formation was quicker in the isolation stress condition such that isolated mice had five times the incidence of metastasis on day 7. The effect of isolation was evident across several measures such that metastasis was more likely in the isolated stress condition even with a smaller tumor challenge; survival time was shorter in the stress mice; and stressed mice did not respond as well to cisplatin chemotherapy. The fact that there was an effect on survival is particularly important since it would suggest that the effects are biologically meaningful to cancer development.

Psychological Stress and Tumor Progression in Humans

The relationship of psychological phenomena with cancer in human subjects has been reviewed in a series of papers presented in *Social Science Medicine* special issue *Cancer and the Mind*, 1985. Geyer (1993: 1545) found more severe life events and chronic difficulties in women with malignant breast cancer compared to women with benign lumps. Similarly, Hatch et al. (1990: 397) presented data which suggested that an increased rate of cancer living near the Three Mile Island nuclear accident was due to the stressfulness of the event and not due to the minimally increased radioactivity levels. While these studies suggest that a possible relation between psychological phenomena and tumor initiation may occur, the results are difficult to interpret given the fact that the data are mostly retrospective in nature. A prospective intervention by Spiegel et al. (1989: 888) examined the effect of a psychosocial intervention on survival time of women with metastatic breast cancer and found that survival time was essentially doubled in the intervention group compared to the control group. While this study did not address the effects of psychological phenomena on the early stages of cancer development, it demonstrated that psychosocial factors can modify the progression of cancer in patients and effect the survival time of patients with advanced disease. A more recent study by Butow et al. (2000: 469) demonstrated similar findings in that they showed that patients, who reported that they had minimized the impact of cancer in their lives, survived metastatic breast cancer longer.

Modifiers of Tumor Progression

A variety of factors are important in stress-induced tumor progression including hormonal modulation, neurochemical modulation, and the use of psychiatric

pharmaceuticals. However, determining the influence of any particular variable is difficult due to the interrelationships of these systems. Additionally, many of these compounds are known to have diurnal, monthly, and yearly cycles which may interact in various ways with their stress-induced patterns of expression thus contributing to the difficulty of elucidating their individual contribution to mediating stress-induced changes in tumor progression.

In spite of the complexity just suggested, it has been demonstrated that a variety of hormonal factors contribute to stress-induced tumor progression including corticosterone, melatonin, estrogen, and prolactin among others. For example, the effects of estrogen have been suggested to be important for some forms of breast cancer. Experimental evidence by several investigators have begun to explore the underlying mechanism of this phenomenon including examination of the effects of tumor exposure during different phases of the menstrual cycle.

In addition to the contribution of hormonal factors on tumor progression, a variety of neurochemical factors act as modifiers of tumor progression including opiates and catecholamines. This line of research is especially clinically relevant since pain management is an important consideration in cancer patients. Gaining an understanding of the central nervous system pathways which can effect stress-induced changes in tumor progression will likely lead to improvements in pain management that do not contribute to tumor development. For example, a study by Gaspani et al. (2002: 18) demonstrated that the analgesic drug tramadol blocked the increased metastatic effect of surgery stress in rats. They suggested this was mediated by natural killer (NK) cells since tramadol increased NK cell activity in nonoperated subjects. This is in marked contrast to the typical suppression in NK activity that has been repeatedly demonstrated with morphine and other opiates used for patients undergoing surgery for cancer.

Furthermore, since the effects of stressors on tumor progression are likely due to the activation of psychological modifiers, it may be possible to intervene by the use of anxiolytic or antidepressant agents. In fact, stress models often demonstrate an amelioration of the detrimental effects of short-term stressors by anxiolytic agents and an amelioration of the effects of long-term or uncontrollable stressors by the use of antidepressant agents.

Hormonal and neurochemical agents may effect tumor progression directly by causing changes in tumor growth and also indirectly by modification of immune-related functioning. In fact, the majority of hormonal and neurochemical changes that occur following stress have known consequences on immune

cells. For example, the effects of opiates on tumor progression have been shown to be related to changes in NK cell functioning. In addition to this, stress effects on tumor progression may be due to changes in NK number as well as due to changes in T and B cell number and/or functioning. Additionally, Wu et al. (2000: 1) have demonstrated that factors such as vascular endothelial growth factor, hepatocyte growth factor, and tumor necrosis factor α may be involved in metastasis by mediating the overexpression of normal endothelial cell functions such as migration, invasion, and tube formation.

Conclusion

The relation of stress to cancer has been suggested since at least the time of Galen and there have been many experimental studies which have attempted to elucidate this phenomenon since then. In testimony to the complexity of the subject, two earlier reviews came to vastly different conclusions as to the role of stress in cancer. In the first review, Sklar and Anisman (1981: 369) present a hypothesis that seems to be well supported by recent findings such that the chronicity of the stressor, the prior experience of the subject, controllability, and social context seem to be the major determining factors in predicting the direction of tumor progression. Additionally, the exact timing of an acute stressor in relation to the presentation of the tumor can dramatically effect the experimental outcome. They suggest that these factors may be producing enhanced tumor development by depleting brain catecholamines and increasing acetylcholine. In the second review, Justice (1985: 108) focused on the types of tumors studied and suggested that tumors be differentiated into viral and nonviral tumors; and the stress response could be thought of as having stages including a rebound or recovery stage following the presentation of an acute stressor. Justice hypothesized that viral tumors were enhanced during stress, were diminished during rebound or recovery to stress, and were the only type of tumors mediated through the immune system. Conversely, nonviral tumors were regulated outside of the immune system and were diminished during stress and enhanced during the rebound to stress. While there continues to be some studies which support this hypothesis, there are many studies that are contradictory. Yet, his review is an important reminder that it is necessary to understand the nature of the tumor under study when designing and interpreting experimental studies. Another review by Demetrikopoulos et al. (1999: 417) presents a more thorough discussion of the relevance of these older reviews to the more recent findings and presents an overview of the current

literature. A review by Ben-Eliyahu (2003: S27) examines a subset of this literature in detail and examines the effects of surgical stress on metastasis. This review explores the effects of cell-mediated immunity and explores possible therapeutic approaches that could be employed to reduce the effects of the surgical stress.

Overall, both physical and psychological stressors have been shown to effect tumor progression with most enhancing tumor growth and/or development. The mediators of this phenomenon are many and include a variety of both hormonal and neurochemical factors that are most likely utilizing central nervous system pathways that are important in anxiety and depression. Furthermore, the mechanisms underlying the effects of hormonal and neurochemical mediators on cancer include direct effects on tumors as well as modification of immunological functioning.

Basic Science Studies

Glossary

<i>11-Deoxycortisol</i>	The immediate steroid precursor for cortisol.
<i>11-β-Hydroxylase</i>	The enzyme responsible for the conversion of 11-deoxycortisol to cortisol.
<i>Cushing's disease/syndrome</i>	An endocrine disease due to excessive cortisol secretion. The syndrome may be due to a pituitary adenoma secreting intact adrenocorticotrophic hormone as well as the larger precursor forms (Cushing's disease; pituitary-dependent Cushing's) or to an adrenal adenoma secreting cortisol (pituitary-independent Cushing's syndrome).
<i>Depression</i>	Major depression as defined by DSM-IV, consisting of a collection of symptoms of at least two weeks duration leading to impairment in day to day functioning.
<i>Hypercortisolemia</i>	Increased plasma cortisol, which occurs in Cushing's patients and in a subset of patients with depression.
<i>Ovine corticotropin releasing hormone (oCRH)</i>	The protein sequence of the hypothalamic CRH found in sheep, in which the hormone was initially isolated.
<i>Panhypopituitarism</i>	A disease characterized by the failure of multiple endocrine systems at the pituitary level, usually secondary to the injury of the pituitary.

Metirapone is an 11-β-hydroxylase enzyme inhibitor that consequently blocks the last step in the synthesis of cortisol in the adrenal, which results in the secretion of 11-deoxycortisol, an inactive adrenal steroid (Figure 1). By blocking cortisol synthesis, metirapone leads to the inhibition of glucocorticoid negative feedback, and this opens up the closed feedback loop of the hypothalamic-pituitary-adrenal (HPA) axis, leading to rebound adrenocorticotrophic hormone

(ACTH) secretion. The presence of an open feedback loop allows the researcher to investigate the hypothalamic and pituitary components of the axis under controlled conditions. Metirapone is used primarily in human studies, whereas adrenalectomy is generally used in studies of experimental animals to accomplish the same goals. However, a few studies have investigated the effects of metirapone in rodents.

Clinical Uses

In clinical endocrinology, metirapone is used primarily in the diagnosis of Cushing's syndrome to distinguish excessive cortisol secretion secondary to excessive ACTH from an adrenal cause for cortisol hypersecretion in the absence of ACTH hypersecretion. In cases of a pituitary adenoma, the ACTH response is augmented tremendously with metirapone blockade of cortisol synthesis, whereas hypercortisolemia from an adrenal adenoma is accompanied by a lesser ACTH response. With the advent of newer, more sensitive ACTH assays, as well as magnetic resonance imaging technology, this test may be less critical to the diagnosis of Cushing's syndrome than previously thought. In addition, metirapone is used in the diagnosis of panhypopituitarism to determine if the patient is capable of responding to a stimulus to the HPA axis. In the past, metirapone has been used as a treatment for hypercortisolemia in Cushing's disease, but the blockade of cortisol is too short term and the side effects limit its usefulness. In addition, one open-label study suggested that it was helpful in patients with depression. A recent placebo-controlled study suggested its potential usefulness in the treatment of refractory cases of major depression; these patients did not necessarily manifest baseline hypercortisolemia. Currently, ketoconazole is the preferred glucocorticoid synthesis inhibitor for the treatment of hypercortisolemia.

Clinical Research Studies

In addition to its standard clinical use, metirapone is a useful research tool. In normal subjects given metirapone between 8 a.m. and 2 p.m., brisk rebound ACTH secretion is observed 2 h following metirapone administration, at which point cortisol levels have fallen to 3–4 μg dl⁻¹ (Figure 2). In normal subjects, the administration of metirapone in the late afternoon and evening (between 4 and 10 p.m.) does not lead to rebound ACTH secretion. This is an indication that hypothalamic drive (endogenous

Figure 1 Administration of metyrapone leads to the blockade of cortisol production and secretion of 11-deoxycortisol, shown for both morning and evening administration in normal subjects.

corticotropin releasing hormone, CRH) is inactive during this time. Alternatively, it may be that the low levels of cortisol still present under metyrapone blockade (between 1 and 2 $\mu\text{g dl}^{-1}$) are able to exert the necessary inhibitory effect through high-affinity mineralocorticoid receptors. Using this same approach in depressed patients, we were able to demonstrate increased hypothalamic drive in the evening in depressed patients, whereas their ACTH response to metyrapone in the morning is relatively the same as controls. These studies suggest that depressed patients demonstrate increased brain CRH in the

Figure 2 ACTH and cortisol response to the administration of metyrapone in the morning and evening in normal subjects. Following the blockade of cortisol production, rebound ACTH secretion is observed in the morning but not in the evening.

evening. A recent report of ours also found a link between excessive response to metyrapone and failure to respond to a 6-week course of fluoxetine. In addition to studies of major depression, metyrapone has been used as a probe of HPA axis function in anxiety disorders, in which the data are mixed. One study of posttraumatic stress disorder showed increased ACTH secretion, but two other studies showed a normal ACTH response. One study of panic disorder also demonstrated a normal response.

Metyrapone has been used by a number of investigators to block glucocorticoid negative feedback in

conjunction with CRH challenge studies. Metyrapone is particularly useful in reducing the effects of high baseline cortisol on the response to CRH and thus evaluating the true corticotroph response. The original studies by de Bold and colleagues demonstrated an increased ACTH response to oCRH in normal subjects given metyrapone compared to the same subjects given oCRH without metyrapone pretreatment. De Bold and colleagues were further able to characterize the effects of cortisol infusion following metyrapone plus oCRH challenge, thus demonstrating that the rise in cortisol induced by oCRH plays a significant role in terminating the ACTH response to oCRH. From these studies, it appears that both baseline cortisol and oCRH-induced increases in cortisol affect the ACTH response to oCRH.

Because patients with major depression demonstrate increased baseline cortisol, their ACTH response to oCRH is decreased. This has been observed in all studies. A number of investigators have examined the response to oCRH challenge under metyrapone in depressed patients. Studies by von Bardeleben and colleagues compared the response to oCRH under metyrapone in depressed patients to that of normal and depressed subjects given oCRH alone and concluded that elevated baseline cortisol was responsible for the diminished response to oCRH in depressed patients. However, these studies did not include normal subjects given oCRH plus metyrapone. Subsequent studies by Young and coworkers and Lisansky and coworkers using controls treated with metyrapone plus CRH confirmed a normal-to-augmented response to oCRH, thus arguing against CRH receptor downregulation in depression.

Metyrapone has also been used to evaluate the kinetics of ACTH inhibition by cortisol following cortisol infusion. Using metyrapone to augment the ACTH response, investigators have infused cortisol to study the fast feedback regulation of ACTH, although metyrapone pretreatment is not necessary to demonstrate fast feedback in humans.

Basic Science Studies

As stated previously, the majority of basic studies used adrenalectomy as a stimulus to ACTH secretion. However, in attempts to reduce the surgical stress involved in adrenalectomy, a few investigators have used metyrapone as a pharmacological adrenalectomy. These studies confirmed that metyrapone administration leads to an increase in both CRH and arginine vasopressin (AVP) in the hypophysial portal blood. Following treatment with metyrapone, a short-term rise was observed in plasma ACTH and β -endorphins

in rats, with a return to normal levels within 4 h. Plasma levels remained low at 24 h. However, by 72 h, ACTH secretion was again elevated. This same pattern was observed to be independent of whether metyrapone was administered during the peak of circadian activation (the evening) or the trough of activation (the morning). The measurement of pro-opiomelanocortin (the ACTH precursor) mRNA in the anterior pituitary and CRH mRNA in the paraventricular nucleus of the hypothalamus also demonstrated at least a 24-h lag time in the effects of metyrapone on steady-state mRNA levels. This lag in the plasma secretory response to the removal of negative feedback in rodents was also observed by Jacobson and colleagues using a different model. This finding contrasts to studies in humans (described earlier) in which rebound ACTH secretion was observed relatively promptly following the removal of glucocorticoid negative feedback during the peak of circadian activation.

Clinical Presentations and Differential Diagnosis of
Migraine
Management
Summary

Glossary

Cephalad Toward the head.
Channelopathy A condition resulting from many scenarios (membrane ion channels that open when they should not, channels that do not open very well or at all, channels that stay open too long, misplaced channels, and a lack of channels or too many channels) that potentially can be deleterious.

Comorbidity

The association between migraine and another condition that is unlikely to be random or causal.

Cortical spreading depression

A local neuronal phenomenon that is elicited by chemical, physical, or electrical stimuli; characterized by a short burst of neuronal electrical activity and followed by a short-lived (minutes) marching wave of slow neuronal suppression.

Incidence

The proportion of new cases of an illness in a defined population over a set time period.

Migraine

A primary headache disorder manifesting as episodic, usually unilateral severe head pain with nausea, vomiting, and light and noise sensitivity.

Neurogenic inflammation

A sterile inflammatory response that is caused by an injurious stimulus of peripheral neurons and that leads to the release of substances (e.g., neuropeptides) that alter vascular permeability.

Phonophobia

An unpleasant feeling when exposed to noise.

Photophobia

An unpleasant feeling when exposed to light.

Prevalence

The proportion of a given population with a disease over a defined period of time. Lifetime prevalence of migraine is the proportion of individuals in the general population who have ever had migraine during their life. Prevalence is the

	average disease incidence multiplied by its duration.
<i>Trepanation</i>	An old surgical procedure in which a hole is drilled or scraped into the skull, leaving the membrane around the brain intact.

Introduction
